The *Times* of May 9 records the striking of petroleum (on the previous day) in a well put down at Darcy, near Dalkeith, on the property of Lord Lothian. The well was originally one of the two selected sites in Scotland in accordance with the Government's drilling programme of 1918, the other, at West Calder, having since been abandoned after being drilled to a depth of 3923 feet. The Darcy well is producing from a sandstone at a depth of 1810 feet, and the oil, though inferior both in quality and quantity to that obtained at Hardstoft, is of paraffin base, somewhat viscous, and carries much gas. Previous to the flow, 8-inch casing had been set in the hole and the oil accumulated afterwards for several hundred feet within it. The bringing in of this well is an event of scientific rather than economic importance, as the initial yield is, commercially speaking, insignificant, while the prospects of the area as a whole are geologically unfavourable to the development of a large oilfield. Hardstoft, the only other producing well in this country, makes an average of 20 barrels per week; the Darcy well is said to yield considerably less *pro rata*. The same number of the *Times* contains the report of a serious announcement concerning the world's oil supplies, made by Prof. Arrhenius, at the close of a course of lectures given at the Sorbonne. Prof. Arrhenius stated that at the present rate of consumption the existing oilfields in the world would, in his opinion, be exhausted within 15 years, an opinion shared by many experts both in this country and in America.

The natural corollary to such a prediction is the recognition of the need for conservation of the world's petroleum resources, especially those of the United States. The development of other sources of fuel, more particularly oil shale, and the ultimate harnessing of forms of energy such as Prof. Arrhenius suggested (plants, watercourses, winds, and the heat of the sun), are matters demanding the assiduous attention of scientific investigators.

THE Governors of the Imperial College of Science and Technology have appointed Sir Thomas H. Holland to be Rector of the College in succession to Sir Alfred Keogh, who is retiring at the close of the Summer term. Sir Thomas Holland is best known by his work in India. Among the many important positions filled by him there were the directorship of the Geological Survey, the presidency of the Industrial Commission and of the Board of Munitions, and more recently membership of the Governor-General's Council. Apart from his important administrative experience his scientific interests centre round geology and oil. He has been a member of many commissions and committees concerned with oil, and for ten years was professor of geology and mineralogy at the University of Manchester. His appointment is also interesting in that he is an old student of the Royal College of Science, having been awarded his associateship in geology of that College, which is now an integral part of the Imperial College, in 1888; and also in that in 1910 he was president of the Old Students' Association of the College, and later a member of the governing body representing the Indian Empire.

THE annual visitation of the Royal Observatory, Greenwich, will be held on Saturday, June 3.

SIR RICHARD GREGORY has been elected president of the Decimal Association in succession to the late Lord Belhaven and Stenton.

AT the meeting of the Royal Society on June 1, the Croonian lecture will be delivered by Prof. T. H. Morgan on "The Mechanism of Heredity."

THE annual Conversazione of the Institution of Electrical Engineers will be held on Thursday, June 29, at 8.30 P.M. at the Natural History Museum, South Kensington, S.W.

THE annual general meeting of the People's League of Health will be held at the Mansion House on Thursday, May 25, at 3.30 P.M. The Lord Mayor will preside, and among the speakers will be Sir Bruce Bruce-Porter, Dr. Farquhar Buzzard, Sir Gilbert Garnsey, Miss Olga Nethersole, and Dr. Saleeby.

THE Linnean Society has recently elected the following as Foreign Members: Lucien Cuénot, professor of zootechnic, entomology, and parasitology in the University of Nancy; Gustave Gilson, director of the Royal Museum of Natural History, Brussels; Jakob Wilhelm Ebbe Gustaf Leche, professor of zoology in the High School, Stockholm; and Dr. Benjamin Lincoln Robinson, Asa Gray professor of systematic botany, and curator of the Gray Herbarium, Harvard University, Cambridge, Massachusetts.

DR. W. BATESON, director of the John Innes Horticultural Institution, Merton, Surrey, has been elected a trustee of the British Museum, to fill the vacancy caused by the death of Lord Harcourt. Other Fellows of the Royal Society who are among the elected trustees of the Museum are Lord Rothschild, Sir Henry Howorth, Sir Archibald Geikie, and Sir J. J. Thomson.

THE *Meteorological Magazine* for April has a note on wireless apparatus for Tristan da Cunha. The Rev. H. M. Rogers, who sailed from South Africa in March to take up the chaplaincy of Tristan da Cunha, has taken with him apparatus with a range of more than 1000 miles. The instruments were presented by the people of Cape Town, who have always shown a keen interest in the loneliness of the island. A meteorological equipment was also presented by the Government, so that Mr. Rogers may send reports of weather conditions in the islets by wireless telegraphy to South Africa and to passing ships; it is thought that the messages will greatly aid weather forecasting.

THE sixtieth birthday of Prof. David Hilbert of Göttingen has been celebrated by the publication of a special number of *Die Naturwissenschaften* (January 27). Opening with a portrait of Prof. Hilbert, it contains an admirable account of his life work by Herr O. Blumenthal, of Aachen. There follow five more specialised appreciations, by different writers, of his work as an algebraist, a geometer, an analyst, a physicist, and a philosopher. Finally, appears a list of Prof. Hilbert's memoirs, eighty-three in all, accompanied in many cases by short abstracts of the results contained in them. Among the ranks of living mathematicians no name is more honoured than Prof. Hilbert's, and this tribute to his fame is well worthy of the occasion it celebrates.

IN July this year, Mr. E. Grey, Field Superintendent of the Rothamsted Experimental Station, will complete fifty years of continuous work at Rothamsted. To mark the widespread appreciation of his valuable services during this long period, it has been decided to raise a fund for a testimonial which shall take the form most agreeable to Mr. Grey himself. There are probably many readers of NATURE who may wish to associate themselves with this testimonial. The director and staff of the station therefore invite subscriptions, which should be sent as soon as possible to the Secretary, Rothamsted Experimental Station, Harpenden, Herts. Mr. Grey's book, entitled "Reminiscences, Tales, and Anecdotes of the Rothamsted Experimental Station Laboratories, Staff, and Fields, 1872–1922," is now in the press and copies can be obtained from the Secretary, Rothamsted Experimental Station, Harpenden, or from Mr. E. Grey, Laboratory Cottages, Harpenden. Price 5*s*. 9*d*. post free. All profits will go to Mr. Grey.

FROM the Report of the Board of the Institute of Physics for the year 1921 we learn that the Institute

now has 400 members, 250 of whom are fellows. The income from subscriptions was a little over 500*l.* and the office salaries 500*l.* During the year the Board formulated a scheme for the publication of a *Journal of Scientific Instruments*, and the Institute has received a grant of 250*l.* from the Department of Scientific and Industrial Research to enable it to produce the first number. The Institute has provided 50*l.* for the expenses of distribution of the 10,000 copies which have been printed, and in a short time the number will be in the hands of those likely to be interested in such a Journal. The price will be 30*s.* per annum if sufficient support is provided by instrument makers, research associations, scientific societies, and the public to justify the regular issue of such a periodical.

The Board of Education has issued a memorandum on the effect of the Summer Time Act on the health of school children. All Local Education Authorities in England and Wales were circularised in May 1921, and only 16 authorities, representing about 127,000 children, failed to reply. Of the 299 authorities from which replies were obtained, 183 authorities, representing 3,227,842 children, are definitely in favour of the Act; 89 authorities, representing 1,600,429 children, consider the Act detrimental, while 27 authorities, representing 232,402 children, have not formed a definite opinion. It should be added that nearly all authorities who hold that the Act is prejudicial to children, state that this is due, not to any defect inherent in the Act itself, but to the fact that parents do not use it rightly. If parental control were properly exercised nearly every authority in the country would approve the Act. The actual (though not the necessary) result of the Act appears to be that large numbers of children lose a valuable hour of sleep, because they go to bed at dusk as before, but have to get up an hour earlier, as the working part of the family rises by the clock. The Board is therefore issuing a circular to the parents of school children, pointing out how important adequate sleep is for the growing child, stating the amount of sleep necessary at the different ages, and supporting the arguments by some common-sense appeals to the parents.

It is announced that the British Association for the Advancement of Science will publish, early next month, "The British Association: A Retrospect, 1831–1921," by the Secretary of the Association, Mr. O. J. R. Howarth, which will present a summary review of the activities of the association in every department of science since its foundation. The production of this volume has been rendered possible through the generosity of Sir Charles Parsons, ex-president, at whose suggestion it was undertaken.

Our Astronomical Column.

A New Variable in Cygnus.—The star B.D. +34° 4217 (position for 1900: R.A. 20h. 54m. 12s. Decl. +34° 47′·4) has been discovered by Mr. Stanley Williams to be a short-period variable (*Monthly Notices*, R.A.S., vol. 82, p. 300). He commenced visual observations on this star with a 6½-in. reflector in October last, and has deduced a light curve which at first appeared to be of an Algol type, but later was found closely to resemble that of β Lyrae. The period is about 15h. 9m. and the range of magnitude 10·42 to 9·93, the magnitude at secondary minimum being 10·15.

The Spectrum of the Corona in 1918.—The expedition sent from the Lowell Observatory to observe the eclipse of June 8, 1918, was stationed near Syracuse, Kansas, and obtained some interesting results in spite of rather unfavourable weather. The equipment consisted of two single-prism and two three-prism spectrographs (one being a slitless instrument). The distribution of coronium was found to be very different from that of hydrogen and helium. The line at λ5303·0 showed that it extended to a distance of about one solar diameter above the sun's surface, and the condensations in the green coronium ring as shown by the objective-prism plates indicated a distribution which was not in any way related to individual prominences. There appeared to be a general correspondence in the distribution of coronium and the main features of the corona, since it was faint or absent in the regions occupied by the polar "streamers" and abundant beneath the main extensions of the corona. The arches over prominences were unusually well developed, but the presence or absence of coronium in them could not be verified. The principal results are described by Slipher in the *Astrophysical Journal*, 55, p. 73.

Determination of Luminosities by Spectrophotometry.—Two new methods for determining stellar absolute magnitudes are described by Lindblad in the *Astrophysical Journal*, 55, p. 85. The first of these is applicable to stars of higher spectral type than those for which Adams's spectroscopic method is available, and is based on the variations, with absolute magnitude, of the energy distribution of the spectrum between H_ϵ and H_ζ. The two regions $\lambda\lambda$3889-3907 and $\lambda\lambda$3907-3935 are compared, and faint stars found to show a considerable relative decrease in intensity of the former region when compared with bright stars. This is probably due to the widening of $H\zeta$ and of some arc lines of iron and silicon. The actual measurements are made by taking a series of exposures of each star on the same plate with decreasing exposure-times. In the series of images thus obtained two are selected such that the intensity of $\lambda\lambda$3889-3907 in one is equal to that of $\lambda\lambda$3907-3935 in the other; and the ratio, E, of the two exposure-times is plotted against the absolute magnitude, M, of the star. Curves are given showing the relation between log E and M for different types, and it is claimed that for types B_8-A_3 absolute magnitudes may be found (with the dispersion used) with a probable error of only $\pm 0{\cdot}4$ mag.

The second method is similar to the first, but is only applicable to stars (types G-M) in which there is appreciable cyanogen absorption. The relative density on either side of λ3889, and between the regions $\lambda\lambda$4144-4184 and $\lambda\lambda$4227-4272 are found and compared as above with the absolute magnitudes of the stars.

Research Items.

MENTAL TESTS AND MENTALITY.—At the present time when, owing to the exigencies of practical life, some method is needed whereby individuals can be selected rapidly and effectively for specific tasks, the question of mental tests is a serious problem. Selection by examination, by influence or personal opinion has been found to be inadequate, and so there is a tendency to expect too much from the alternative method known as mental tests. In *Psyche* (Vol. II. No. 4) Prof. Pear raises some very interesting problems connected with such tests. He insists that intelligence tests indicate only one kind of mental capacity; they are an attempt to provide a quantitative indication of some mental trait. In practical testing, however, the tester often ignores the characteristic apparatus possessed by the examinee; even though two people may be assigned like marks for a test, in actual life it may matter seriously whether the result was attained by the use of visual imagery, kinæsthetic imagery, verbal formulæ, or imageless thinking. Again, the attitude of mind of the examinee must be considered; a genius might display apparent lack of intelligence because he saw in the problem many more complications than the ordinary person, and the typical extrovert will react quite differently from the typical introvert. Lastly, the author discusses the problem of stupidity both intellectual and emotional, the latter type having been very much neglected. The paper is both critical and suggestive, and will be of interest to workers in this field whether from the educational or industrial aspect.

LIGHT REQUIREMENTS IN HOSPITALS.—At a joint meeting of the Illuminating Engineering Society and the Royal Society of Medicine on April 27 the lighting of hospitals was discussed. The subject presents many interesting problems, and has not yet received sufficient attention. Mr. J. Darch, who presented the introductory paper, showed a variety of illustrations of methods of lighting wards devised to avoid glare from lights shining in the eyes of patients—apparently a common fault in hospitals. He also discussed the lighting of operating tables where somewhat complex requirements exist, including a very high illumination, freedom from troublesome shadows cast by the person of the operator, and elimination of the possibility of dust falling from the fixture during an operation. A value of not less than 25 foot-candles on the operating table was suggested. Reference was also made to natural lighting, the somewhat revolutionary proposal being made that the operating theatre should be located at the top of the building so as to secure maximum daylight. A number of medical men and ophthalmic surgeons joined in the discussion. Mr. Conrad Beck contributed an analysis of the requirements to be met in microscope illumination. The suggestion was made that "artificial daylight" units would prove very serviceable in cases where correct appearance of colours forms an important feature in diagnosis. Mr. J. B. Reiner showed some compact forms of inspection lamps where the provision of a sufficiently bright and uniform illumination, without striations, presents difficulties. Prior to the discussion a series of queries relating to problems met with in hospital lighting had been drawn up and circulated, and Mr. Gaster suggested that these might form the subject of study by a small joint committee.

THE ORIGINS OF EXISTING CORALS.—Prof. P. C. Raymond ("The History of Corals and the 'limeless oceans,'" *Amer. Journ. Sci.*, vol. 202, p. 343, 1921) traces the hexacoralla back to Walcott's *Mackenzia costalis* from the Middle Cambrian of Burgess Pass, British Columbia, a limeless form first described as a holothurian, and referred to the actinians by H. L. Clark. Its modern representative is found in Edwardsia, an inhabitant of sandy shores. Prof. Raymond regards all the Palæozoic corals that adopted the habit of secreting—or, from the present point of view, excreting—calcium carbonate as tetracoralla. These were killed off in the cold waters of the Permian glacial epoch, leaving the Edwardsian line to pass on into a large number of hexacorallan types with calcareous skeletons, which first become prominent as reef-builders in Middle Triassic times. At this period, the warmer waters contained more salts, and the sedentary habits of the actinians decreased their power of elimination. These seem large conclusions to found upon the impress of a soft-bodied organism of Cambrian age; but palæontology at present glows warmly through the use of well-controlled scientific imagination.

GEOLOGY OF WESTERN SOUTHLAND, NEW ZEALAND.—The Geological Survey of New Zealand continues, in Bulletin 23, its admirable practice of combining geological description with illustrations of the scenery of the country. The fascinating South Island bids fair to be as well "visualised" by those who cannot travel as are the west central States of North America; and each new Bulletin issued by Mr. P. G. Morgan makes one wish that New Zealand could be floated nearer to its antipodal colleague on some favouring current of the "sima" (see Wegener's views, NATURE, vol. 109, p. 202). Prof. J. Park in No. 23 describes part of Western Southland, including Lake Te Anau, which simulates a fjord among the mountains. The deep dissection of the early Cretaceous peneplain that was worn across the folded masses of the New Zealand Alps has formed noble ravines like that of the Clinton River (Pl. III.), where intrusive diorites and granites, probably of Permian age, come to light. These valleys have been carved along Pliocene lines of fracture. Though Prof. Park gives a general summary of the geological history of New Zealand (pp. 25-28), he touches very briefly on the formation of the arc of which the axis of the islands forms a part. He significantly refers the folding and fracturing to compressive stresses set up by the sinking of the adjacent troughs; but he inclines to regard these troughs as very ancient and persistent features. One would like to know if the present islands, as a ridge between the great eastern and the shallower western deeps, owe their existence above sea-level to a Pliocene creep of the ocean-floor resisted by an unseen extension of the Australian block.

CLOUD FORMS.—An article by Prof. W. J. Humphreys of the U.S. Weather Bureau on "International definitions and description of cloud forms, and supplementary remarks" is given in the March number of the Journal of the Franklin Institute. The article, which is continued from the February number, is based on a lecture on "Fogs and Clouds," given before the Section of Physics and Chemistry of the Franklin Institute on January 5 last. The different forms of cloud are well illustrated from photographs, many of which are new so far as cloud illustrations published on this side of the Atlantic are concerned. Cirrus clouds, from their light formation, are usually very difficult to represent in published form, but the illustrations given are good. Cirrus, which is the highest cloud, is said to occur at a height, approximately, of 5 miles in polar regions, 7 miles in middle latitudes, and 9 miles within the tropics. Many of the photographs

were taken from Mount Wilson and other heights. A cumulus formed by convection over fire is exceedingly good, and several lenticular cloud specimens are of interest; types are given of the funnel cloud or tornado cloud. The height of clouds is discussed, and it is said that they are lower during winter than during summer, due to the difference in relative humidity. The extension of our knowledge of the upper air has added much to the better understanding of cloud development.

Electrolytic Dissociation.—The Journal of the American Chemical Society for April contains an interesting paper by Prof. T. W. Richards and A. W. Rowe on the heats of neutralisation of alkalies with monobasic acids at various dilutions. As is well known, the approximate equality of the heats of neutralisation of strong acids by strong bases, indicating that the same reaction took place in all cases, namely, the union of hydrogen and hydroxide ions to form undissociated water, was one of the strong arguments for the theory of electrolytic dissociation put forward by Arrhenius. The careful measurements described in the paper show that the heats of neutralisation are slightly different, but since they all tend to the same limit with increasing dilution this is almost certainly the result of slight differences in the extent of ionisation of the different acids, bases, and salts. In solutions containing 100 grm. molecules of water to one of acid and base, the heats of neutralisation varied from 13·75 to 14·09 kilogrm.-calories. The heat of formation of water from its ions is found by slight extrapolation to be 13·62-13·69 kilogrm.-calories at 20°, in good agreement with the value 13·7 adopted by Arrhenius. These results would seem to rule out the assumption made by Ghosh and others that these electrolytes are all equally dissociated at the same dilution, and in a paper in the same journal by Prof. J. Kendall the theory of Ghosh is also adversely criticised from other points of view.

The British Beet-Sugar Industry.—In 1745 the Berlin chemist Margraaf discovered sugar in the beet, and in 1812 Napoleon laid down 75,000 acres for the cultivation of beet and established six centres of instruction. This was the result of the Continental blockade. Immediately before the outbreak of war in 1914, France and the United States each had half a million acres under sugar-beet, Germany had a million acres, and Austria, Belgium, Denmark, and Holland also made important contributions to the industry. Great Britain had only one factory, at Cantley in Norfolk, under Anglo-Dutch control. In the Journal of the Society of Chemical Industry for April 15 an account, with excellent illustrations, is given of the beet-sugar works at Kelham, Notts, owned by Home-Grown Sugar, Ltd. This works, which was designed by a French firm, and is almost entirely staffed by French workmen and managers, was the result of a grant of money from the Treasury. Up to date there has been a large deficit on the working of the factory, but as a result of the arrangement with the Government to remit the duty until the company is in a position to produce a total of 50,000 tons of sugar a year, it is hoped that progress will be made. The process is identical with that used in the North of France. Sugar-beet has been cultivated on 230 acres, and some 2300 acres have been grown locally by farmers, an average of 5·5 acres each. The sugar content of the roots has reached 15·92 per cent. The roots are washed, sliced mechanically, and treated with water in diffusion apparatus at about 70° C. The extract contains about 12·5 per cent of sugar, and the residue, after drying and mixing with molasses, is sold for stock feeding. The aqueous extract is treated with milk of lime and then with carbon dioxide to precipitate the lime. The clear liquor, after filtration, is treated with sulphur dioxide, evaporated *in vacuo*, cooled, and the crystals drained in centrifugal machines.

A New Desensitiser.—We learn from the *British Journal of Photography* of May 5 that Dr. E. König, of the Hoechst firm of Meister, Lucius, and Brüning, who was associated with Dr. Lüppo-Cramer in his work on desensitisers of photographic emulsions, has continued the work on this subject. The practical result is that he has obtained a desensitiser fully equal in its effects to phenosafranine and without some of its disadvantages. The new desensitiser is called "Pinakryptol" and is a greenish-grey mixture of two desensitisers. One part is dissolved in 5000 parts of water for use, and its notable advantage is that it has no staining action on gelatine or celluloid or the fingers or nails of the user.

Petrological Microscopes.—We have received from Messrs. James Swift and Son, Limited, a catalogue of their petrological microscopes. The excellence of their work has earned them a well-deserved reputation which is still maintained. A number of types are described in the catalogue, some with a rotating stage and others with rotating nicols as originally designed for the firm by Mr. Dick. The former include the "Primex" for the use of elementary students, the "Advanced Student," the "Petros," and the "Survey." The "Petros" has a hinged analyser, which can be brought into position above the ocular. This has the advantage that a quartz-wedge can be introduced in the focus of the ocular. In the remainder the analyser is inserted in the lower end of the body tube, but a second analyser, which can be placed above the ocular, can be purchased as an accessory. In the "Advanced Student" the convergent system fits into a sleeve above the polariser, but the top lens can be removed if a less convergent system be desired. This arrangement can, however, be replaced by the convenient swing-out screw focussing adjustment which is fitted to the more expensive "Petros" model. The "Survey" is distinguished by its well-equipped substage. In all except the "Primex" there are two Bertrand lenses for the observation of interference figures, one at the upper end of the tube for measuring comparatively small crystals, and the other just above the objective, giving a much larger image. A more advantageous course is to employ, instead of a Bertrand lens, an auxiliary lens above the ocular. The light coming from a small crystal or part of a crystal, which it is desired specially to examine, can first be isolated by a perforated diaphragm in the focus of the ocular and the auxiliary lens then placed in position, when the interference figures can be observed unaffected by extraneous light. This procedure was recommended by a committee of the British Science Guild, and excellent auxiliary lenses of this description have been prepared by Messrs. Swift, which might have been expected to have had a place in this catalogue. Two types of microscope with rotating nicols are described, the well-known "Dick" microscope, and the "Grabham-Dick," distinguished by the triple nose-piece beneath the stage, which makes it possible to place three different types of condenser in position in turn. Full particulars are given, in the concluding pages of the catalogue, of different objectives, nose-pieces, centring objective changes, and other necessary or commonly employed accessories manufactured by the firm. It should have been stated in the case of quartz-wedges whether they are graduated to show the relative retardation at different points.

The Rat and its Repression.

By ALFRED E. MOORE, Hon. Director of the Incorporated Vermin Repression Society.

RATS have for more than three thousand years been regarded as noxious vermin by man. Boelter[1] reminds us that the Egyptian cat, *F. Caffra* (*Caligata* or *Maniculata*) was a domestic animal in Egypt twenty centuries B.C. and that it was held in the highest reverence as a natural protector of grain from rats and mice. Boelter relates how, when Ptolemy was doing all he could to conciliate the Roman power, a Roman accidentally killed a cat, and Diodorus Siculus, an eye-witness, tells how nothing, not even the terror of the Roman name, could save the unlucky Roman from punishment. To-day, when the rat army numbers almost countless legions, we find an apathy that is appalling, a stagnation of effort which is allowing the rat to encircle the earth, and like a creeping paralysis to leave death and destruction in its trail.

It is not so important to fix geographically or historically the origin of the rat, as it is to realise the fact that this rodent now inhabits practically every place where man has a dwelling, and that of all animals it is most fitted by nature to serve as a human scourge. Apart from the astonishing prolificacy of the rat, the animal is furnished by nature with first-class engineering and excavating tools in the shape of wonderful hand-like paws, a pair of incisor teeth of razor-like cutting power and hardness, a tail which serves a variety of uses, and a brain nimble, cunning, and educable. These advantages plus a courageous and adaptable disposition have served to make the rat ubiquitous.

It has been urged that all rats are cannibals and that the brown rat (*Rattus Norvegicus*) in England has driven out the black rat (*Rattus Rattus*), but too much reliance cannot be placed on these assumptions, for rats are cannibals only when driven by unsatisfied appetite, and it is doubtful if the number of black rats in any area in England is such as to diminish the food supply of the brown rat and force it to become an active cannibal, or, on the other hand, that the sexual appetite artificially stimulated under the Rodier system can diminish appreciably the number of rat hordes.

It is, of course, fairly easy to invite a charge of exaggeration when dealing with the rat, for the pest is without doubt a grave menace; it has been said by Dr. Khunart that the rat must be destroyed, or it will destroy man. Insistence on the serious character of the problem makes it extremely difficult, however, to wage an effective war on the animal; for it is easy to secure the label "crank" and to lead the man-in-the-street to remark that, if it be true that the rat is such a terrible fellow, "it's a wonder we are alive." Prominent leaders of thought in the veterinary world regard the rat as a disease carrier *par excellence*, and I am convinced that further research will establish the rightness of many suspicions, but for the moment let us consider the nature of proven charges. We know, for example, that rats transmit plague, trichinosis, malignant jaundice, parasitic mange, and rat-bite fever, and we know that these maladies are serious diseases. They are, of course, calculable in effect, but there are other human ills directly attributable to the presence of the rat, such as loss of sleep through nervousness, fright, etc., and these ills are burdensome in so far as that they contribute materially to the sum of factors in physiological fatigue and therefore occasion incalculable loss of human efficiency.

Economically, the rat is a charge upon the resources of the nation, which is only measurable in figures too great to be comprehended by the casual student. We know that rats commence to breed when three months old, that the female litters from 6 to 12 times a year, and that the litter consists of from 6 to 12 young; therefore, we have a population of about 1000 rats from one pair of rats in 15 months, and as a rat costs approximately 1½*d.* per day for food it will readily be seen that we are paying too dearly for this pest. How much we are paying will be more clearly realised when we remember that it is generally agreed that the number of rats equals the human population; in some cases the rat population is considerably greater, as at a sugar plantation in Porto Rico, where the population numbered less than five hundred people and a six months' rat drive accounted for 25,000 rodents killed. Bearing these numbers in mind, and taking the population of the British Isles as being about 47,000,000, we get a rat cost of as much as 75,000,000*l.* per annum after deducting ½*d.* per day per rat for garbage eating.

This is not, however, the total amount of taxation the rat imposes upon us, for it is my experience that the animal does an enormous amount of damage in pursuit of its food, and in poultry yards its depredations are very considerable. "Lantz (U.S.A.) quotes a Washington merchant to the effect that rats gnawed a hole in a tub containing 100 dozen eggs, and within a period of two weeks carried away 71 dozen without leaving either shell or stain." Cases are not rare where rats have disposed of half a lamb in a night, and it is an undoubted fact that if meat is condemned as tuberculous or unfit for food, rats seem to have an uncanny instinct for finding and consuming such portions of the carcases as are diseased.

It must not for one moment be imagined that fear of the rat is a fad, nor is it peculiar to the medical profession: medicine, hygiene, and commerce all have contributed men with international reputations—Crichton-Browne, Andrew Balfour, Arthur Shipley, Glen Liston, Mark Hovell, Akin, Pasteur, Creel, Emil Zuschlag, Hinton, Bruce Bruce-Porter, James Cantlie, Frederick Hobday, Banister Fletcher, Castellani, Nathan Raw, Sydney Hickson, Tanner Hewlett, and Lords Denbigh, Aberconway, Lambourne, Ernle, and others too numerous to mention have joined their voices to those of the informed public and members of Parliament in a call for rat repression, as a measure of public safety.

It is significant that the first determined effort to deal with the rat in England found definite shape in ordinances made in various parishes in 1740 and again in a Bill introduced into the House of Commons by Sir Chas. B. McLaren in March 1909, and reintroduced by him into the House of Lords, some ten years later, where he sat as Lord Aberconway. Although in common with America, Japan, Denmark, Sweden, Barbadoes, Antigua, and Hong Kong, we in England have now an anti-rat law, there is much amendment required to make it effective.

[1] "The Rat Problem," by Wm. Boelter. John Bale, Sons, and Danielsson, Ltd.

There are no financial provisions for the Rats Act's working to be found in the Act; it is punishable with a fine to harbour rats, yet reinfestation of a cleared habitation is not punishable, nor is trafficking in rats a crime. These weaknesses are being remedied in a Bill being drafted by the Incorporated Vermin Repression Society to amend the existing Act. The I.V.R.S. memorialised the League of Nations, and incidentally the memorial was signed by leaders of all shades of thought, with the view of securing an International Conference to deal with rats and shipping (the existing regulations being chaotic and tending to discriminate against this country) and to give a ruling on the vexed question of the employment of virus.

The virus question is one that should be settled without delay. Those—like the I.V.R.S.—who oppose its use, argue that it is unsound in principle to permit the unrestricted use of living virus, or germs, of mouse typhoid or any other disease which might possibly become communicable to man, and that, moreover, it is a waste of money and opportunity to create a race of rats immune to the effects of virus in the process of killing what is, after all, an infinitesimal proportion of the rat population. Attempts to get manufacturers interested in the production of virus to agree to a round table conference with unbiassed bacteriologists, pathologists, Government representatives and business men, have unfortunately, so far, been unsuccessful.

The question is often asked—"What is the best method of destroying rats?" There is only one answer—"There is no *best* method of destroying these pests." Rat destruction is a problem of urgency, and also one of extreme difficulty, and a moment's reflection shows that this difficulty cannot be dismissed with a shrug of the shoulders, because the rat is far too clever to be caught except in negligible numbers by any crude method. It is an omnivorous feeder, and since the rat's diet comprehends bacon, bananas, eggs, lamb, young chicks, offal, bread, sponge-cakes, young rabbits, young game, biscuits, human flesh, apples, sweetbreads, corn, bulbs, and other eatables too numerous to mention, it is hopeless to pin one's faith to poisoning, since all poisoning, that is to say, effective poisoning, is a matter of baits. Again, this method of destroying rats demands fool-proof preparations, which limits the field in this respect; obviously it is dangerous to place poisons such as arsenic, strychnine, antimony, phosphorus and the like in places accessible to children or domestic animals; therefore, for all practical general purposes we are limited to barium carbonate, squill, and sodium fluoride. Cats and dogs are very useful, but it is a mistake to assume, as does one port authority, that an excellent sufficiency of cats is a good insurance against rats; as a matter of experience it is nothing of the kind, for, like practically all domesticated animals, the cat is companionable, and unless it has a spare diet, and is deprived of the association of too many of its kind, it becomes a hunter after the fleshpots of Egypt rather than a menace to rats. Ferrets are useful only in the hands of practical rat-catchers; for in unskilled hands they get lost. Nevertheless, since they are useful in skilled hands, they may render excellent service to the community when they are associated with a game terrier in an anti-rat club, and such clubs should be a feature in every village and rural town. Gassing, too, has its advantages, sulphur dioxide being perhaps the safest to use, but as a lethal agent it is inferior to chlorpicrin gas. The U.S.A. Government report favourably on a gas called cyanogen-bromide. There is much to be said for the raising of the status of those who are engaged in the war against rats; for modern drainage systems, while aiming at efficient sanitation, undoubtedly provide excellent facilities for rat locomotion, and tend to defeat the object of rat-weeks by allowing the hard-pressed rats of one district to escape to another district where the rat-week is next week. The vast emporiums, too, provide problems in rat repression which no ordinary rat-catcher can grapple with effectively. To sum up, if rats are to be appreciably diminished in number it is imperative that—

(1) An International Commission be created to extract the best of all existing rat laws and codify them in such a manner as to ensure their being concurrently effective in all countries, and in all ships and vehicles of water transport.

(2) Our own rat laws be amended: (*a*) to make rat trafficking a crime; (*b*) to make rat reinfestation a crime; (*c*) to make financial provision for the carrying out effectively of the rat law; and (*d*) to make it an obligation upon the Ministry charged with the administration of the Act to enforce its being carried out by the authority concerned.

(3) All *bona fide* rat-catchers be registered and given instruction in elementary pathology, sanitary engineering and hygiene, and certificates be issued to competent and honest persons engaged in this business, withdrawable publicly in the Press in the event of petty larceny, offences against the Rats Act, or for other specified reasons.

(4) The question of the use of virus should be settled, and whatever conclusion is arrived at in this regard be given the widest publicity.

(5) Twice a year all British authorities be compelled to co-operate and synchronise their efforts in rat destruction, and during the period, public lectures on rat destruction, rat proofing, and the necessity for eliminating possible rat-breeding grounds, be organised by the authorities.

(6) The authorities responsible for the zoological laboratories of all universities, colleges, and institutes be invited to set apart a portion of their time for the teaching of economic biology in so far as it concerns the rat, the diseases it carries, its movements, the nature and extent of its depredations, its natural enemies, and the known poisons which are safe to use, this with the view of discovering improved methods of ensuring its destruction.

(7) In all elementary schools pupils be taught the life-history of the rat, regarding the rat as man's natural enemy, the toxicity of the various raticides in common use, the value of the barn owl (*Strix Flammea*), the ferret, the weasel, the common kestrel, and the pine marten, the use of baits, varnishes, traps, the progress made by gassing as a method of rat destruction in ships and in places where it is possible to confine the gas, and the best methods of destroying rats (by water-flooding) in their runs, an effective method of killing rats in the country.

(8) All local authorities should frame their bye-laws so as to encourage rat proofing, and all employers of labour should exhibit in canteens, etc., a card, 12 in. × 10 in., warning their employees against leaving about the debris of food, and a reminder: "No scraps, no rats."

It cannot be urged too strongly that of all remedial measures against the rat, the most important are rat proofing and the withholding of food and water, especially water, for rats can exist much longer without food than without water.

Science and Gas Warfare.[1]

I LOOK upon it as a great honour to have been invited to come here to-day, and I appreciate the compliment which has been paid me. It was my privilege to be associated with many of the leading British men of science during the war, and, if I may say so without presumption, I regarded them with the greatest admiration. I was intimately connected with certain phases of their work, and I was also brought into contact with the war work (carried out on the same lines) of most of our allies, as well as of our late enemies: and while implying nothing derogatory to the latter, I have no hesitation in declaring that in the matter of practical achievement British men of science were second to none.

The war was one in which science played a part which increased progressively in importance: and the Empire owes a debt, the extent of which perhaps it does not fully realise, to the able scientific workers who gave their services—often in an honorary capacity—in solving the various vital problems which were put before them—problems in preventive medicine, optics, sound-ranging, aeroplane design, chemical warfare, and so on: and to the scientific institutions all over the country which provided them with facilities for their researches.

It is not surprising to find that this College, with its Imperial associations and great record of public service, took a leading part in this work—the work of winning the war. A prominent feature in the Nominal Roll of the College is the variety of the service which was given by its past and present students. Their names appear in every department of army activity, but more especially in the various branches of my own Corps, the Royal Engineers. We have been called the scientific Corps; but while not pretending that this is an accurate description, we are, and always have been, at any rate the link between the army and the scientific world, and I think I can claim that we are very receptive of all scientific proposals and alive to their developments. Many of the students of this College served in that branch of the Corps with which I was most intimately concerned, and the names of some of them are engraved on this tablet.

Owing to the secrecy which it was necessary to maintain during the war, the general public has still, I believe, little idea of the prominent part which chemical warfare played on the field of battle on the Western Front. Between the Battle of Loos, in September 1915, and the armistice, the activity of the Special Brigade was almost incessant, and gas attacks were carried out on an average on two nights out of every three during the whole period. Some 800 separate attacks were made—against about 25 by the Germans against us—and nearly ten thousand tons of gas were liberated, quite apart from the work of the artillery: and many were the variations practised in the form of attack, as regards tactics, mechanical appliances, and meteorological conditions.

The enemy's casualties from these gas attacks probably numbered between 100,000 and 200,000, amongst whom the percentage of mortality was very high. These operations were carried out, for the most part, by young students fresh from civil life, who had had little preparation for the work and practically no military training whatever. In spite of the heavy artillery bombardments to which they were subjected—the retaliation for which each gas discharge was the signal—these young men combined with their technical skill a standard of personal courage worthy of veteran soldiers: and many distinctions were conferred on them, including the Victoria Cross. But it was not only in the front-line trenches that British men of science distinguished themselves in France. When the Germans launched their first gas attack against us in April 1915 our soldiers were unprepared and quite unprotected: and it must remain one of our proudest memories that they stood at their posts, and hundreds of them died there: it was due to the initiative and the energetic action taken by your Rector, Sir Alfred Keogh, then the head of the Medical Service at the War Office, and the steps devised by Prof. Haldane of Oxford, Prof. Baker and the late Prof. Watson of this College, and Prof. Jones of Manchester—then a private in the London Scottish—that the lives of thousands of British soldiers were saved in the course of the next few weeks. The protective appliance then extemporised was gradually developed in efficiency, chiefly by the late Lt.-Col. Harrison, until it became eventually a very perfect apparatus, millions of which were issued to the American and Italian armies as well as to our own.

This, however, was not the only scientific work undertaken for the protection of our troops. Knowing that we were only on the threshold of scientific discovery in its relation to gas warfare, we were always keenly sensitive to the appearance of any new chemical substance on the field of battle. In order to recognise it immediately it appeared, and to take the necessary steps to combat it, a very efficient chemical intelligence department was organised—quite separate from that which served the General Staff. A gas officer was appointed to each division in the field, one of whose duties it was to report all German gas attacks and bombardments—by telephone, and during its actual progress if it was an important one. If any novel symptoms of gas poisoning appeared anywhere on the front an able physiologist, who made a speciality of this work, went immediately to investigate them. If a new gas shell was suspected, samples of earth and water from the shell craters were collected for analysis, and an unexploded shell-case was located and dug up as soon as possible and sent in to a central laboratory for examination.

Opening these shells, the contents of which were often under pressure, was difficult and dangerous work: and I have little doubt that it was owing to his personal devotion to it, and the complete disregard of his own safety, that the late Prof. Watson, who was the Director of this laboratory, sacrificed his health, and eventually his life. I think it would interest you to hear that such was the efficiency of this chemical intelligence service that when the Germans first introduced mustard gas—then practically an unknown substance—warnings were telegraphed to all our armies, tabulating the injuries caused and the precautions which should be taken to avoid them, while an approximate analysis of the contents of one of the shells had also been made—all between 24 and 48 hours of its first use. When we came to summarise our knowledge of mustard gas at the end of the war, after a further 18 months' experience of it, it was found that there was little that could be added to the statement originally issued.

In conclusion, I ought not to omit reference to the devoted work done at home in connection with chemical warfare in the various research laboratories and munitions factories all over Great Britain. One of

[1] Address by Col. C. H. Foulkes when unveiling the War Memorial of the Royal College of Science on March 29.

our gas factories was closed on certain occasions for days at a time because most of the workers were put out of action, suffering from gas poisoning: there were other similar incidents, and in a number of cases men lost their lives; which shows that service at home was by no means without its risks. In fact, I might almost say that work in a poison gas factory entailed suffering from gas poisoning sooner or later.

In research work, Profs. Baker and Thorpe were very prominent throughout the whole period of the war. They, with other eminent men, gave themselves whole-heartedly to this work, to their own financial disadvantage, and without the prospects of reward which the successful soldier has in view. In science, at any rate, there was no profiteering. A lady of this College, Dr. Whiteley, introduced the use of "S.K."—symbolising South Kensington—a substance that was largely used against the Germans—as well as a new explosive.

In all the preliminary physiological tests, of course, animals were used; but volunteers were never wanting for the more important experiments in the lethal chamber: and at one time many of the experimental staff at Porton were in a constant state of ill-health owing to the trying nature of this work. One gallant action worthy of record was that of Mr. Barcroft of Cambridge, who, in order to confirm a theory which had an important bearing on our gas tactics, entered the lethal chamber together with a dog, both being entirely unprotected, and remained there while exposed to prussic acid gas until the dog died.

All honour, then, to the distinguished scientific workers of our nation in general, and of this College in particular, staff and students, who responded to the call of patriotism on the battlefield, in the committee-room, the research laboratory, and the munitions factory; but, above all, let us hold in grateful remembrance those whose names are inscribed on this tablet, who not only served their country to the best of their ability, but who gave their lives in doing so.

The Evolution of Plumage.[1]

THE paper by Prof. Ewart referred to below contains much good and new matter, but the good observations are not exactly recent discoveries, whilst the new conclusions and speculations are rather contestable, or at least startling.

The bulk of the paper is very technical, but some of the generalisations concerning the evolution of the coat or coats of feathers of birds never fail to interest a wider circle of readers. The first coat of the young chick is composed of structurally rather simple little feathers, the Neossoptiles or nestling feathers; the final or finished feathers were called Teleoptiles. The first set is structurally continuous with the next growing set or generation. Then it was found that in the majority of birds not one but two nestling coats were successively developed, both in structural continuity with each other (henceforth distinguished as Proto- and Mesoptiles; and the latter passing into the Teleoptiles).

These several sets or generations vary much in relative importance, time of their emergence or growth, size and temporary functions, in the different groups of birds. For example, whilst the first set forms the duckling's first and effective jacket, it is the second set which in the penguins makes a very woolly and warm coat which lasts the youngsters many months, until these fluffy down-like feathers are supplemented by typical adult feathers. Moreover, in the duckling this second set is in the interesting condition of reduction, being practically crowded out of existence between the first and the third set. It depends upon the group of birds whether and how and to what extent these Mesoptiles become vestigial.

Again, while in ducks and penguins—in fact, in the overwhelming majority of birds—the difference between their nestling coat and the final dress is enormous (let us remember the callow blind-born nestling of a thrush, with a few large wavy tufts, before the final feathers begin to sprout), in the cassowaries and emus the differences between the successive coats are reduced to a question of mere size. In short, the variations are almost endless and still promise many new discoveries, all the more interesting when correctly correlated with the bird's ecology. Indeed, here is a wide and fertile field for fascinating speculation. Let us see how Prof. Ewart has tackled the matter. The chapters dealing with a more general account of the evolution of the plumage are an instance of that kind of "Natur-Philosophie" which, entranced by the new Darwinism, did not allow itself to be hampered by facts nor to be checked by the perhaps equally sanguine speculations of others.

Although the earliest birds known are the two specimens of Archæopteryx from the upper Jurassic, our author states that at the beginning of the Jurassic age the coat of birds may have consisted only of Protoptiles; and the scene of the dawn of feathers of such low order is set in a land with desert climate, cold and dry, atmospheric conditions which would engender feathers. The dryness would cause the hypothetical feather "filaments" or cryptoptiles to split or fray into a kind of brush, and "whatever bird or beast became warm-blooded would appreciate an overcoat." Presumably the creature became heated by its attempts to flutter, and the increased temperature made it liable to catch cold and call for a feather coat. Thus a teleological unscientific notion is preferred to the suggestion that a gradually improving coat (and frayed brush-like scales would be less heat-conductive than ordinary reptilian scales) might induce first stable and then permanently increased blood-temperature. Surely the important feature would be the thermostatic result, resulting incidentally from the development of a better non-conducting coating.

In any case this first set of little Protoptiles formed at best a poor sort of flimsy overcoat. When, however, the climate changed from cold and dry to cold and damp, "during perhaps a cold phase of a glacial epoch," the coat was changed into the Mesoptile coat by the lengthening of the previously existing branches, or barbs, of the brush, and by the sprouting of new additional barbs. At any rate thus was evolved the thick, fluffy, warm coat of the young penguins, and it "is probably as useful now to the penguin chicks hatched within or near the Antarctic circle as it was when originally acquired during perhaps a cold stage of a glacial epoch."

Later, as the climate improved [interglacial] this fur-like second coat was in most other birds more or less suppressed [perhaps it proved too hot] and a third coat was constructed out of what gradually improved into feathers proper, which in turn were differentiated into downs and contour feathers, and some of these became, through use, etc., specialised into remiges and rectrices. At last there was a chance for a flying bird. Ostriches and similar birds perhaps never did

[1] "Nestling Feathers of the Mallard," by Prof. J. Cossar Ewart, Proceedings, Zoological Society of London, 1921, p. 609.

live in a cold damp climate, and consequently never went through the intermezzo of a "British warm."

But which glacial epoch wrought all these miracles? The author, surely, does not mean the Permian glaciation; and certainly geologists tell us there was none until towards the end of the Tertiary. Perhaps the penguins had a Jurassic glacial epoch in their Antarctic realm, while owls and petrels, which, by the way, have as thick and fluffy and long-lasting Mesoptile coats as any penguins, owe these coats to our Pleistocene bad times. We can scarcely date these birds back into early Jurassic times like the penguins, which until their first interglacial ease-off must have waddled about without feathers proper, all their lives long moulting from one thick Mesoptile coat into the next, generation after generation. This truly startling picture results from the confusing of generations of feathers, which are ontogenetic items, and stages in the evolution of the plumage, which are phylogenetic conceptions.

Archæopteryx likewise does not fit into this view, with its highly specialised remiges and rectrices, of late Jurassic date, and certainly long before penguins came into existence.

Apropos of the question of the origin of feathers from scales, we are told that the conversion of his Cryptoptiles (consisting apparently of hollow epidermal cones) into the Protoptiles took place "in some incomprehensible way," and that the Protoptiles "in some way soon acquired the chief characteristics of true feathers." Perhaps it was a case of miraculous mutation? But why incomprehensible, considering that there are at least two reasonable possible explanations, the only difficulty being which to choose. What is less comprehensible is that the author did not refer simply to that résumé (itself a large essay) by that experienced referee Prof. Keibel, in "Ergebnisse . . .," 1896, supplemented more recently by Schleidt (1913) and Steiner (1918), who adds a literature list well-nigh complete and appalling by its size.

H. F. G.

The Advance of Heliotherapy.

By DR. C. W. SALEEBY.

THE treatment of disease by sunlight is the newest of old things. It was systematically practised by Hippocrates, the Father of Medicine, and perhaps we need not trouble ourselves with questions of priority in our own times. At any rate, the first clinic for the heliotherapy of surgical tuberculosis was opened by Dr. A. Rollier at Leysin in 1903, and at last it would appear that his methods are to be followed throughout the world. Already in France and Italy the sun cure is practised, and I recorded lately in NATURE (March 2) the finding of many heliotherapeutic institutions on the Riviera, from Cannes to San Remo. The city of Lyons wisely sends its sick children to the Villa Santa Maria at Cannes, and the Italians have recently established the Istituto Elioterapico which I found outside San Remo a few weeks ago. In our own country we have Sir Henry Gauvain at the Treloar Hospital, Alton and Hayling Island, and Dr. Gordon Pugh, at Queen Mary's Hospital for Children at Carshalton. In the United States, Rollier is being followed at Perrysburg, near Buffalo.

Now there comes an admirable volume[1] which clearly presages the advance of heliotherapy into Spain. The number of the journal in question is devoted to a series of articles in Spanish by Dr. Rollier and his assistants at Leysin. First of these is a paper by Dr. Rosselet, a physicist, on the scientific bases of heliotherapy, and Dr. Amstad contributes a paper on the sun cure of non-tuberculous diseases. We shall do well not to associate the sun cure exclusively with tuberculosis nor solely with the proved antiseptic power of sunlight. The recent American work, both at Columbia University and Johns Hopkins Hospital, has shown that sunlight has potent influences upon nutrition and metabolism, and is capable, for instance, of preventing and curing rickets in a fashion hitherto unsuspected. Amstad refers to rickets, of course, but he is evidently not acquainted with this new American work.

The publication is completed with a series of well-produced plates which illustrate Rollier's methods and show, in several "before and after" photographs, the all but miraculous results which he habitually obtains.

Madrid, like Munich and Mexico City, is a city which teaches us that abundant tuberculosis may occur even at high altitudes. Even "Sunny Spain" needs the lessons of heliotherapy. At Mentone, a few weeks ago, myself in broad and ravishing sunlight, I saw a cobbler at work in a dark room, lit by a miserable oil-lamp, the rays of which ill served to illuminate his work. Answers of this order serve as reply to those who ask why, for instance, if the sun be such a preventive, there is any tuberculosis in India.

In his fine article in this present publication, Dr. Rollier insists, as ever, upon the superior value of the early morning sun. This point needs perpetually to be made. We tend to associate light and heat; so that, last year, the late Prof. Benjamin Moore actually asked, in the *Times*, whether "too much light and heat" may not be bad for us. The question is illegitimate. Light and heat must be distinguished. In Canada, according to my own observation there, it is the combination of light and cold that contributes to the superb Canadian physique and vitality. In Switzerland the same is true, and Leonard Hill has shown us the physiological basis of this valuable combination. But when thoughtless clinicians expose cases of pulmonary tuberculosis, for instance, to sunlight in warm weather, perhaps in the afternoon, perhaps even with exposure of the chest, and achieve only fever and hæmorrhage for their unfortunate patients, we are told that heliotherapy is useless in phthisis.

It is certainly high time that the fundamentals of the biology and physiology of light should be well and truly laid. Dr. Rosselet, in his interesting contribution, does not convince us that any one, as yet, really knows how sunlight achieves its results, but we shall expect to place heliotherapy upon broad and deep foundations when the committee lately appointed by the Medical Research Council gets to work. Meanwhile we must hope for English translations of "La Cure de Soleil" and the rest of Rollier's works, so that the present tragic farce of the treatment of tuberculosis in this country, with its desolating results, may yield to the intelligent use of sunlight.

The Universities and the Publication of the Results of Research in America.

ONE of the principal subjects dealt with by the Association of American Universities in their conference last November was the publication of the results of research. Scientific and learned periodicals are numerous in the United States, and there has until the present been but little co-ordination. "The American Chemical Society," says the editor of the *Yale Review*, "now has under its management three journals: a monthly devoted to the theoretical aspects of the subject, another monthly devoted to industrial chemistry, and *Chemical Abstracts*, which reviews twice a month all publications carrying new contributions to chemistry in its various phases. The question of a similar consolidation has reached at least the stage of discussion in several other National Societies in order, not only to avoid duplication, but also to reduce overhead costs, and to bring together where it may be readily examined material that now lies hidden in hundreds of places and so may be easily overlooked." He suggests that universities might support periodicals published by such national societies in preference to establishing their own separate periodicals, and in particular, that instead of requiring dissertations for the doctor's degree to be published *in extenso* they should cause them to be "cut down to the bone" and the skeletons thus obtained to be given to the national societies for publication in their journals. The societies on their part might, he suggests, have their printing done by the University Presses.

An interesting sketch was given by the Director of the Wistar Institute for the Advancement of Biological Science of the operation since 1908 of a "plan for assembling and publishing a number of national zoological journals under one central management." So successful has this proved that the combined annual sales of five journals has increased from 1410 to 5286 copies, while the income has been gradually overtaking the cost, notwithstanding a lavish distribution of free copies, notably 5000 dollars' worth to the principal libraries of Europe—a policy begun immediately after the armistice was signed and to be continued for five years.

The factors of success are thus summarised: a whole-hearted co-operation of the men of science interested, whether as author, editor, publisher, or reader, a centralised management looking ever to prompt publication and extensive distribution with efficiency and economy, concentration on a group of journals limited to one field of research, and guarantee both financial and scientific of an endowed institution devoted to the same field of science. A feature of the Institute's methods of publishing the results of research is the system of "Bibliographic Service Cards." These include the author's abstract as well as complete bibliographic references, and an announcement of the date when the complete article will appear. They are issued fortnightly to subscribers to all the Institute's journals, and extra copies are often distributed for advertising purposes.

University and Educational Intelligence.

MANCHESTER.—The Council of the University has appointed Dr. Robert Robinson to the chair of organic chemistry which was vacant owing to the appointment of Prof. A. Lapworth to the chair of chemistry. Prof. Robinson graduated at Manchester University in 1905 with first-class honours in chemistry and was a graduate scholar and Le Blanc medallist. As research student, and later as a lecturer in organic chemistry in the University, a remarkable series of papers on natural plant products were produced in conjunction with Prof. W. H. Perkin and others. His synthetic work has also been singularly skilful. His work has been often concerned with the processes taking place in the living organism and has in many directions shown the way to development in biochemistry. In addition to his academic work, Prof. Robinson, as Director of Industrial Research to the British Dyestuffs Corporation, has gained experience of working conditions especially valuable to such an important centre of the dyestuff industry as Manchester. Prof. Robinson has previously held chairs of organic chemistry at Sydney and Liverpool, and the chair of chemistry at St. Andrews. He was elected a Fellow of the Royal Society in 1920.

THE Delegacy of the City and Guilds (Engineering) College has appointed Prof. C. L. Fortescue, of the Royal Naval College, Greenwich, to succeed Prof. T. Mather, who is resigning the chair of electrical engineering in the College at the close of the present session.

THE Dr. Edith Pechey Phipson post-graduate scholarship of the London (Royal Free Hospital) School of Medicine will be awarded in June. It is open to all medical women, preferably coming from India, or going to work in India, for assistance in post-graduate study. It is of the annual value of 100*l.*, for a term not exceeding three years. Applications for the scholarship must reach the Warden and Secretary of the School, 8 Hunter Street, W.C.1 by May 31.

RECENT appointments to the staff of the Technical College, Bradford, include Mr. R. E. Stradling, as head of the department of civil engineering in the college, and Mr. H. J. B. Chapple, as lecturer in electrical engineering.

APPLICATIONS are invited for the Ray-Lankester Investigatorship at the Marine Biological Laboratory, Plymouth. The post is of the value of 100*l.* and is tenable for fifteen months, out of which the investigator will be required to devote five months at the laboratory to some subject of marine research. Applications should be addressed to the Director.

A CONFERENCE of representatives of the Universities of Great Britain and Ireland was held on Saturday last, May 13, at University College, London, under the presidency of Sir Donald MacAlister, vice-chancellor and principal of the University of Glasgow. The discussion on advanced study and research was opened by Dr. J. C. Irvine, vice-chancellor and principal of the University of St. Andrews. Dr. Irvine expressed the opinion that research should be controlled in every university by a board or standing committee, with power to recommend changes in the teaching staffs of departments actively engaged in research, to allocate money voted for research purposes, and to consider such questions as travelling and publication grants.

Dr. L. R. Farnell, vice-chancellor of the University of Oxford, who opened the discussion on specialised study, stated that the idea of having one university for physical science and another for the humanities would be fatal to the cultivation of both branches of knowledge. On the other hand, it must be recognised that by reason of their surroundings, some universities were peculiarly fitted for certain studies. Mr. Fisher joined in this discussion, emphasising the growing need for co-operation between the universities, in respect of the distribution of studies according to the particular advantages of each. It was suggested that

a committee of vice-chancellors should investigate claims for additional endowments by special departments and inquire whether the transference of trust funds to different subjects within the university was desirable or whether the migration of students requiring special subjects could be facilitated. Sir Henry Miers, vice-chancellor of Victoria University, Manchester, was emphatic on the point that higher education of the right type could be given only by universities or institutions of similar standing.

IF the number of suitable applicants is sufficient, the Board of Education will provide during the summer, courses of instruction of two weeks' duration for teachers of engineering science and electrical engineering in technical schools. The standard of the work will be that of the "National Certificates" in engineering of ordinary grade, but advanced treatment will be accorded to certain sections of the work. The courses will start on Saturday, July 22, and will end on Saturday, August 5. The courses will be held in Oxford, in the University Engineering Building, the University Electrical Laboratories, and in the new laboratories of the City of Oxford Technical School. The instruction in engineering science will be given by Prof. F. C. Lea, of Birmingham University, and that in electrical engineering by Prof. W. M. Thornton, of Armstrong College University of Durham, each of whom will have the assistance of a staff of tutors, lecturers and instructors. Teachers who wish to apply for permission to attend either course must fill up and return form 972 T/Engineering as soon as possible, so as to reach the Board's office not later than Monday, May 29.

MR. J. W. BISPHAM, of the London County Council service (Technology Section), has been appointed principal of the Borough Polytechnic Institute, to fill the vacancy caused by the retirement of Principal C. T. Millis. He will take up his duties in September.

IN Bulletin No. 6, 1921, of the United States Bureau of Education, published for the guidance of students in other countries contemplating advanced study or research in the U.S.A., particulars are given regarding the graduate schools of 28 universities, including, *inter alia*, admission requirements, periods of study for degrees, noteworthy facilities for particular lines of graduate study (equipment and research funds, library facilities, and facilities for publication of research results), expenses of tuition and board and lodging. The graduate school now usually co-ordinates into one administrative unit all the advanced teaching and all the facilities for original research provided by the university. To obtain a master's degree, one year (Yale and Johns Hopkins—two years) of post-graduate study devoted, as a rule, to not more than three subjects, including one "major," is usually required, while for a doctor's degree the minimum period is usually three years. Most universities require the dissertation for the doctorate to be published. The requirements for the Ph.D. degree parallel closely those proposed by the German universities, but attempts have recently been made to insist on a somewhat longer scholarly preparation and a more substantial thesis. Each university generally awards to graduate and professional students a number of fellowships and scholarships carrying stipends ranging from 100 to 600 dollars, the holders of which are sometimes required to do one to six hours' teaching weekly. Foreign students will usually find it necessary to spend at least a year in residence at an American university before qualifying for one of these grants. The enrolment in graduate courses in the United States increased from 4340 in 1893 to 16,470 in 1916.

Calendar of Industrial Pioneers.

May 18, 1747. Bernardo Zendrini died.—One of the most celebrated Italian hydraulic engineers of the eighteenth century, Zendrini was also a mathematician and was one of the first to apply the infinitesimal calculus to practical problems. As mathematician and engineer to Ferrara, Modena and Venice he carried out many works connected with the rivers and ports of north-east Italy.

May 19, 1907. Sir Benjamin Baker died.—Born in 1840, Baker was apprenticed at the Neath Abbey Iron Works in South Wales, and after gaining experience as a civil engineer became an assistant to Sir John Fowler, with whom he was afterwards in partnership. Among the great works he was associated with were the Forth Bridge, the Assouan Dam, the Central London Railway, and the Avonmouth Docks. As one of the leading engineers of his day he served on the Ordnance Committee, the Engineering Standards Committee, was elected a fellow of the Royal Society, and in 1895 served as president of the Institution of Civil Engineers. A memorial window to his memory has been placed in the north aisle of Westminster Abbey.

May 21, 1826. Georg von Reichenbach died.—A famous German mechanician and instrument maker, Reichenbach was born in 1772 at Durlach. In his youth he spent some time at Boulton and Watt's works at Birmingham, and after his return to Germany was employed with his father in the manufacture of munitions. In 1800 he invented a dividing machine; the transit circle was re-introduced by him, and he collaborated with Utzschneider, Fraunhofer, and Ertel.

May 22, 1900. William Lindley died.—Trained as a civil engineer under Francis Giles, Lindley worked under Brunel on the Thames Tunnel, and in 1838 became engineer of the Hamburg and Bergedorf railway. He was afterwards responsible for the sewage works, the water works, and many of the engineering schemes which turned Hamburg into one of the greatest modern seaports.

May 23, 1800. Henry Cort died.—The inventor of the important process of puddling and also of the grooved rolls for manufacturing wrought iron, Cort, between 1765 and 1775, made a fortune as a navy agent in Surrey Street, the Strand. Stimulated by the dearness of Russian iron, he then made experiments on iron-making and had works at Fareham and Gosport where, in 1783, he brought out his great inventions, but at the same time reduced himself to poverty. His inventions added enormously to the wealth of the country, and the puddling process supplied all the malleable iron for our engines, railways, and iron ships till the introduction of the Bessemer process of making mild steel.

May 23, 1915. Pierre Emile Martin died.—A native of Bourges, and born in 1824, Martin in the early 'sixties began experimenting on the manufacture of steel in a small Siemens regenerative furnace, and in July 1865 took out his patent for the process in which pig-iron, scrap steel, and iron oxide are melted together on an open hearth. Till the introduction of the basic-lined furnace of Thomas and Gilchrist, the Martin—or Siemens-Martin process, as it is known in England—made little headway against the Bessemer process. By 1913, however, of 74 million tons of steel produced only 30 millions were produced in Bessemer converters and the remainder by the Martin process. Martin reaped no pecuniary advantage from his work, but in 1910 a fund was raised for him, and a few weeks before his death he was awarded the Bessemer medal.

Societies and Academies.

LONDON.

Royal Society, May 4.—Sir Charles Sherrington, president, in the chair.—C. **Shearer**: On the heat production and oxidation processes of the echinoderm egg during fertilisation and early development. The heat production during fertilisation and early development of the egg of *Echinus miliaris* has been measured by the differential micro-calorimeter, and the oxygen consumption and carbon dioxide output by the differential manometer. In one hour, 1 million unfertilised eggs (8 mgrm. egg N.) consumed 15·1 c.mm. of oxygen at standard barometric pressure and 14·5° C., and gave off 0·067 grm. cal. of heat. In a similar interval the same quantity of fertilised eggs consumed 86·4 c.mm. oxygen and liberated 0·397 grm. cal. of heat. The ratio of the heat production in one hour to the oxygen consumption gives a calorific quotient *Q*, which is 3·07 in the unfertilised and 3·22 in the fertilised developing egg-cell. Thus very little of the chemical energy liberated as the result of fertilisation is expended in bringing about the visible morphological structure of the developing ovum. The heat liberation, oxygen consumption, and carbon dioxide output of the ovum after fertilisation rise progressively during development, reaching the highest point when the free-swimming stage is reached.—Johan **Hjort**: Observations on the distribution of fat-soluble vitamins in marine animals and plants. The periodical changes in the size and quality of fish at different seasons of the year are associated with changes in the content of fat. In cod the changes in quality are demonstrated by inspection of the size of the liver, which is 50 per cent. "cod-liver oil." The liver of full-grown cod during the summer season, when the fish was feeding, weighed three times as much as in winter, during the spawning season. Seasonal variations in quality do not coincide with temperature variations, nor, in the case of the cod, with the availability of the animals which serve it as food. The distribution of fat-soluble vitamin in green algæ (Ulva), diatom-plankton, shrimps and prawns, and hard roes of herring and cod was studied. These substances had a marked effect in re-starting and maintaining the growth of rats, previously on a diet free from fat-soluble vitamin.—H. **Hartridge** and R. A. **Peters**: Interfacial tension and hydrogen ion concentration. The drop-weight method, which gives results similar to the capillary height and ripple methods, was employed for measuring the interfacial tensions. A decrease in interfacial tension between a fatty acid or glyceride and aqueous fluids occurs with increasing alkalinity of the aqueous fluid. It depends upon the concentration of the fatty substance in the oil phase, the presence of a certain concentration of alkali in the aqueous phase, and the hydrogen ion concentration at the interface. Only substances having a COOH group (free or combined, as tri-glyceride) gave these changes.—W. **Cramer**, A. H. **Drew**, and J. C. **Mottram**: Blood-platelets: their behaviour in "vitamin A" deficiency, and after "radiation," and their relation to bacterial infections. The absence of the fat-soluble vitamin from the diet leads, in the rat, in every case to a progressive diminution in the number of blood-platelets known as thrombopenia. Thrombopenia occurs before any obvious signs of ill-health appear. When profound thrombopenia has been established, addition of the missing vitamin A to the diet is usually followed by rapid increase in the number of platelets up to the normal. Exposure to radium produces lymphopenia, which is characteristic of vitamin B deficiency, and also, with large doses, thrombopenia. Animals generally recover rapidly if the application of radium is discontinued. If the number of platelets is reduced below a certain critical level—about 300,000 in the rat—the resistance of the animal to infection is greatly diminished and infective conditions develop spontaneously. Alterations in local or general resistance to the infection are associated with local or general changes in distribution of the platelets.

Royal Microscopical Society, April 19.—Prof. F. J. Cheshire, president, in the chair.—R. S. **Ludford**: Morphology and physiology of the nucleolus. Of the various functions which have been attributed to the nucleolus, recent work emphasises that it (1) represents secretory substances or enzymes elaborated by the chromosomes (chromatin) to bring about metabolic processes in the cytoplasm; (2) is the accumulation of waste products of nuclear activity which when extended into the cytoplasm are broken down with the liberation of energy, which is utilised for other purposes; (3) stands in some functional relationship to the morphological changes which take place in the chromosomes at different periods of cellular activity. There is considerable evidence in favour of each of these theories as to the function of the nucleolus.

Physical Society, April 28.—Dr. Alexander Russell, president, in the chair.—T. **Smith**: The position of best focus in the presence of spherical aberration. Focal variations of phase in the presence of spherical aberration are calculated directly from the axial intersection points of rays of known inclination. The new graphical method employed shows that the focus for which phase variations have a minimum value may be found and interpreted when the finiteness of the wave-length is disregarded.—F. **Twyman** and J. **Perry**: The determination of the absolute stress-variation of refractive index. The Hilger interferometer is employed in determining the stress-optical coefficients. Young's modulus of elasticity and Poisson's ratio are determinable simultaneously.—C. J. **Smith**: An experimental comparison of the viscous properties of (*a*) carbon dioxide and nitrous oxide, and (*b*) nitrogen and carbon monoxide. Direct comparisons have been made by observing the time required by a mercury pellet to force an equal volume of gas through a capillary tube at atmospheric and steam temperatures. The times of fall for each gas are equal at 15° C. and 100° C., and hence it is shown that the viscous properties are identical over this range. The absolute viscosity has been obtained by comparison with air, and the mean area of collision deduced by using Chapman's formula.—F. **Twyman**: An optical sonometer. The object of this instrument is to furnish graphs of the pressure variation in sound waves. The sound is directed by a trumpet upon a celluloid membrane a fraction of a wave-length of light in thickness, which is silvered at a point between its centre and periphery. Rays from a pointolite lamp are concentrated on the silvered surface, and are reflected thereby through an ordinary and a cylindrical lens on to a photographic strip carried by a spring-driven chronographic drum. The duration and incidence of the photographic exposure are controlled by adjustable devices revolving with the drum. The constants of the membrane can be determined by measuring its curvature with an interferometer when it is being stressed by gravity, pneumatic pressure or electrostatic attraction. Good sound records can be obtained so long as the pitch of the sounds investigated differs considerably from the resonance pitch of the membrane, which is of the order of 200 per second.

CAMBRIDGE.

Philosophical Society, May 1.—Prof. H. F. Baker in the chair.—H. **Lamb**: Waves of permanent type at the interface of two liquids.—A. E. **Western**: The number of primes of the form n^2+1.—S. **Chapman** and T. T. **Whitehead**: The influence of electrically conducting material within the earth on various phenomena of terrestrial magnetism.—Mr. **Ince**: The impossibility of the coexistence of two Mathieu functions.—V. **Trkal**: A general condition for the quantisation of the conditionally periodic motions with an application for the Bohr atom.—C. D. **Ellis**: Interpretation of the β-ray and γ-ray spectra. Taking a general view of a β-ray disintegration and of the radiations that accompany it, the β-ray line spectrum is entirely secondary in origin and due to the conversion of monochromatic γ-rays. The general β-ray spectrum and these γ-rays are the primary phenomena. This theory accounts for the thorium-*C* and radium-*D* spectra. Frl. Meitner's theory is unlikely to be correct; it offers no explanation of the general β-ray spectrum; it predicts that the total number of electrons emitted should be less than the number of atoms disintegrating; and, finally, certain lines in the radium-*B* spectrum should be primary and characteristic of the radium-*B* nucleus and therefore should not appear in the spectrum excited in lead by the γ-rays of radium-*B*. These lines, however, have been observed.

DUBLIN.

Royal Dublin Society, April 25.—Dr. G. H. Pethybridge in the chair.—W. E. **Adeney**, A. G. G. **Leonard**, and Miss A. M. **Richardson**: On the aeration of quiescent columns of distilled water and of solutions of sodium chloride. Columns of de-aerated distilled water and of sodium chloride solutions up to ten feet in length were exposed to a slow current of dry air for periods of 14-56 days. Samples were withdrawn from various depths and the nitrogen content determined. It is found that aeration is effected by the exposed layer mixing with the unexposed portions of the water to depths of at least 10 feet. This process is caused by the downward "streaming" by the constantly changing layer of water exposed to the air. It proceeds more rapidly, and more uniformly, to depths of at least 10 feet, in salt water than in fresh water. The rate at which "streaming" proceeds depends largely upon the rate at which the concentration and cooling of the surface layer is brought about by evaporation, and proceeds more rapidly at temperatures at and above 10° C. than below it. It is less rapid, and less uniform downwards to 10 feet deep, and probably to greater depths, at temperatures below 8° C., especially in fresh waters. The rate of mixing also depends upon the concentration of salt in solution. The optimum concentration appears to be about 1 per cent. sodium chloride.—T. A. **McLaughlin**: Cataphoresis of air bubbles in various liquids. Air bubbles show no cataphoresis in the following liquids: methyl, ethyl, and butyl alcohols, xylol, benzine, toluene, bromobenzine, benzyl alcohol, benzaldehyde, aniline, cinnamic aldehyde, ethyl malonate, lactic acid, oleic acid, ethyl acetate, and turpentine. It was not possible to trap an air bubble in acetone and volatile liquids such as carbon disulphide. In impure acetone foreign matter moved towards the positive pole. In distilled water, air bubbles moved towards the positive pole; in impure benzine, towards the negative pole; in "pure" nitrobenzine, to the negative pole. In impure nitrobenzine the motion may be to either pole.

PARIS.

Academy of Sciences, April 24.—M. Emile Bertin in the chair.—E. **Goursat**: The theory of integral invariants.—P. **Marchal**: The metamorphosis of the females and hypermetamorphosis of the males in the Coccidia of the Margarodes group. Both males and females pass through three forms—first a primary hexapod larva capable of migration; then a cystoidal larva adapted to life fixed to a plant; and, thirdly, a hexapod form, at which stage the development of the female is arrested. The male continues to develop through two or three other forms before reaching the winged stage.—L. **Lumière**: Capillary movement, diffusion, and displacement. A study of flow through filter paper and cotton strips used as siphons. The flow of liquid increases with the height of fall up to a certain distance and then remains constant. Some practical applications are given, including washing photographic negatives and precipitates with minimum quantities of water. A negative 9 cm. by 12 cm. can be washed completely in 15 minutes with less than 30 c.c. of water.—E. **Vessiot**: Surfaces generated by circles.—E. **Cartan**: The equations of structure of generalised space and the analytical expression of Einstein's tensor.—E. **Nörlund**: The interpolation formula of Newton.—B. **Gambier**: Point correspondence of two surfaces and a class of surfaces analogous with isothermal surfaces.—A. **Pictet** and J. H. **Ross**: The polymerisation of lævoglucosane. Lævoglucosane, heated to 140° C. in the presence of a trace of zinc chloride, polymerises in accordance with the equation $nC_6H_{10}O_5 = (C_6H_{10}O_5)_n$ in a few minutes. Different polymers are obtained by varying the pressure: at 15 mm. of mercury $n=2$ and the product is dilævoglucosane $(C_6H_{10}O_5)_2$, at atmospheric pressure $n=4$, under 4·6 atmospheres $n=6$, and at 13·3 atmospheres $n=8$.—P. **Gaubert**: The liquid crystals of calcium phosphate.—P. L. **Mercanton**: The magnetic state of arctic basalts. Since the Tertiary period the magnetic inclination of the earth in the northern regions would appear to have changed its sense: to complete the proof an examination of antarctic larvas is desirable.—S. **Stefanescu**: The phylogeny of *Elephas antiquus*.—A. **Carpentier**: The conifers and ferns of the Weald of Féron-Glageon.—J. **Maheu**: A retarded regeneration of moss. A detailed description of the growth of a specimen of *Barbula muralis*, after remaining 14 years in a state of absolute dryness.—G. **Nicolas**: Remarks on *Narcissus tazetta*.—G. **Malfitano** and M. **Catoire**: Amylocellulose considered as a compound of silicic acid and amylose. Experimental evidence that silica is an essential constituent of amylocellulose.—A. **Vila**: The influence of heat and of some solvents on the viscosity of horse serum. The coagulating effect of acetone, analogous with that of heating, can be reduced or even avoided altogether by taking certain precautions.—Y. **Manouélian**: Histo-microbiological researches on general paralysis. Existence of the treponeme in the cytoplasm of the nerve cells of the cerebral cortex.

FRIDAY, MAY 19.

INSTITUTE OF TRANSPORT (at Institution of Civil Engineers), at 10 A.M.—D. H. Davies: The Finance of the Modern Highway: A Problem and a Solution.—Prof. J. Carlier: Foreign Railway Practice.—Col. J. W. Pringle: Safety in Railway Operation.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—W. Rushton: Further Contributions to the Biology of Freshwater Fishes.—Prof. J. H. Priestley: Toxic Action of Illuminating Gas on Plants (with Demonstration).

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—Annual General Meeting.

INSTITUTE OF TRANSPORT (at Royal Society of Arts), at 5.—F. V. Russell: The Operation of Heavy Suburban Passenger Services on a Steam Railway, with particular reference to Density of Service, Terminal and other Facilities.

INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section) (Annual General Meeting), at 7.—A. H. Reeves: The Elimination of Atmospherics in Radio-telegraphy.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) (Annual General Meeting) (at Langham Hotel), at 7.15.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—H. Dewey: The Sources and Transport of Non-local Rocks in the London Area.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—F. W. G. Clark: Engineering Business in China.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir William Bragg: The Structure of Organic Crystals.

SATURDAY, MAY 20.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. O. W. Richardson: The Disappearing Gap between the X-ray and Ultra-violet Spectra. II. Photo-electric Methods.

MONDAY, MAY 22.

ROYAL SOCIETY OF MEDICINE (Odontology Section) (Annual General Meeting), at 8.—E. Sprawson: The Significance of the Extra Cusp commonly found on the Antero-internal Aspect of the Maxillary First Permanent Molar in Man.—H. C. Malleson: Some Notes on Dental Histology.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—H. Lee Shuttleworth: The Border Countries of the Punjab Himalaya.

TUESDAY, MAY 23.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. Bulloch: Tyndall's Biological Researches and the Foundations of Bacteriology (2). (Tyndall Lectures.)

INSTITUTE OF PHYSICS (Annual General Meeting) (at Royal Society), at 5.—Sir J. J. Thomson: Presidential Address.

ROYAL SOCIETY OF MEDICINE (Medicine Section) (Annual General Meeting), at 5.30.—M. P. L. Violle: A Practical and Accurate Method of Estimating Diuresis.—Dr. W. Hunter: The Nervous Disorders of Severe Anæmias in relation to their Infective Lesions and Blood Changes.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: Report on the Additions to the Society's Menagerie during the month of April 1922.—Rev. H. N. Hutchinson and E. Godwin: Exhibition of a Plaster Cast of a Model Reconstruction of the Marine Reptile *Peloneustes philarchus*, a Pliosaur from the Oxford Clay.—Sir Sidney F. Harmer: Commerson's Dolphin and other Species of Cephalorhynchus.—C. F. Cooper: Miocene Proboscidia from Baluchistan.—R. I. Pocock: The External Characters of Scarturus and other Jerboas compared with those of Zapus and Pedetes.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—T. Thorne Baker and L. F. Davidson: Spectroscopic Measurements of the Hydrogen Ion Concentration Colour Changes in Recent Indicators.—K. C. D. Hickman: The Dyeing of Silver Iodide with Methylene Blue, including:—(*a*) A Method of measuring Small Quantities of Methylene Blue occluded by Silver Iodide Precipitate; (*b*) The Tanning of Gelatine by Development Action and its Influence on the Process of Dyeing.—E. L. Turner and C. D. Hallam: The Function of the Flash Exposure in Three-colour Work. (Experiments in half tone, 3rd series.)—A. C. Banfield: The Trist Three-colour Exposure Camera.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Dr. B. Malinowski: Theory and Practice of Witchcraft in Eastern New Guinea.

SOCIOLOGICAL SOCIETY (at 65 Belgrave Road, S.W.1), at 8.15.—E. Betham: The National Housing Policy: A Common Sense View.

WEDNESDAY, MAY 24.

LINNEAN SOCIETY OF LONDON, at 3.—Anniversary Meeting.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Very Rev. Dr. W. R. Inge: Theocracy (1). Theocracies in General.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.

ROYAL SOCIETY OF ARTS, at 8.—G. Fletcher: The Natural Power Resources of Ireland.

FELLOWSHIP OF MEDICINE (at Royal Society of Medicine), at 5.—Sir St. Clair Thomson: The Surgical Anatomy of the Nose and Accessory Sinuses.

THURSDAY, MAY 25.

ROYAL SOCIETY, at 4.30.—*Probable Papers.*—Prof. C. H. Lees: The Thermal Stresses in Solid and in Hollow Circular Cylinders concentrically heated.—B. F. J. Schonland: The Scattering of β Particles.—N. K. Adam: The Properties and Molecular Structure of Thin Films. Part II. Condensed Films. Part III. Expanded Films.—E. Wilson: The Susceptibility of Feebly Magnetic Bodies as affected by Compression.—S. F. Grace: Free Motion of a Sphere in a Rotating Liquid parallel to the Axis of Rotation.

INSTITUTION OF MINING AND METALLURGY (Special General Meeting) (at Geological Society), at 5.30.—H. R. Sleeman: The Re-establishment of the Gold-basis of Currency.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Annual General Meeting.

ROYAL MICROSCOPICAL SOCIETY (Metallurgical Section), at 7.30.—L. S. Ward: Notes on Etching and Etching Re-agents.

ILLUMINATING ENGINEERING SOCIETY (Annual Meeting) (at Royal Society of Arts), at 8.—Report of Council;—at 8.30.—Sir John Herbert Parsons: Presidential Address.

ROYAL SOCIETY OF MEDICINE (Urology Section) (Annual General Meeting), at 8.30.—Prof. F. Hobday: Urinary Calculi in Animals.—K. Walker: The Genital System of the Rhinoceros.

FRIDAY, MAY 26.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Sir Thomas W. Arnold: Indian Painting and Muhammadan Culture (Sir George Birdwood Memorial Lecture).

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Dr. F. W. Aston: Atomic Weights and Isotopes (Lecture).

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section) (Annual General Meeting), at 5.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.—Dr. R. Dudfield: Reforms needed in the Notification of Tuberculosis.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. W. E. Dalby: The Internal Combustion Engine: Its Influence and its Problems.

SATURDAY, MAY 27.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Hugh Allen: Early Keyboard Music (1).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, MAY 19.

LONDON SCHOOL OF ECONOMICS, at 5.—Dr. P. Giles: Modern Views of Indo-European Origins (2).

UNIVERSITY COLLEGE, at 5.15.—A. E. M. van der Meersch: Simplified Solutions for B.M. and S.F. Values for Rolling Loads (2);—at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (3).

BIRKBECK COLLEGE, at 6.—Dr. E. J. Russell: Recent Work with regard to the Influence of Soil Conditions on Agriculture (2).

GRESHAM COLLEGE, at 6.—Sir Robert Armstrong-Jones: Physic (4) (Gresham Lectures).

MONDAY, MAY 22.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. F. Widal: Anti-anaphylaxie (in French).

KING'S COLLEGE, at 5.30.—Prof. F. H. Edgeworth: The Development of the Head Muscles of Vertebrates (1).

TUESDAY, MAY 23.

UNIVERSITY COLLEGE, at 5.—Sir Arthur Shipley: Insects and Disease (4).

KING'S COLLEGE, at 5.30.—Prof. H. Wildon Carr: The Principle and Method of Hegel (4). The Concrete Universal.—Prof. F. H. Edgeworth: The Development of the Head Muscles of Vertebrates (2).

WEDNESDAY, MAY 24.

KING'S COLLEGE, at 4.—Dr. A. Harker: Tertiary Igneous Action in Britain (2).—Prof. F. H. Edgeworth: The Development of the Head Muscles of Vertebrates (3).

SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. R. A. Nicholson: The Idea of Personality in Sufism (2).

UNIVERSITY COLLEGE, at 5.15.—Dr. D. H. Scott: The Early History of the Land Flora (5).

THURSDAY, MAY 25.

CHELSEA PHYSIC GARDEN, at 5.—E. A. Bowles: Superstitions of Early Herbalists: particularly the Doctrine of Signatures, illustrated by Living Plants (Chadwick Lecture).

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 5.—Prof. E. H. Starling: Some New Experiments on the Kidney.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. H. Vaquez: De l'Érythrémie (Maladie de Vaquez-Osler) (in French).

KING'S COLLEGE, at 5.30.—Prof. F. H. Edgeworth: The Development of the Head Muscles of Vertebrates (4).

UNIVERSITY COLLEGE, at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (4).

FRIDAY, MAY 26.

The Dark Ages: A Survival in Kentucky.

It is probable that Mr. Bateson would not have been surprised to find that some points in his address on "Evolutionary Faith and Modern Doubts," delivered at Toronto before the American Association for the Advancement of Science (see NATURE, April 29), gave rise to a certain amount of criticism and discussion; but we should have thought that neither he nor any one else could have anticipated that this able deliverance would be used as a text on which to found a violent attack upon the teaching of evolution in the schools of a civilised State. Such, however, is the fact; and the attempt to force this remarkable form of prohibition upon the Kentucky Legislature was only defeated, after repeated divisions, by a single vote. That an occurrence of this kind should be possible at the present date may well cause astonishment, and the accounts which have reached us of the discussion which took place in the House of Representatives reveal an amount of ignorance and prejudice on the part of responsible legislators which would be ludicrous if it were not lamentable. One of the promoters of the measure, we are told, who spoke for nearly an hour amidst cheers and applause, made a division between "sheep" and "goats," placing the principal opponents and various zoology text-books in one class, and the Bible, the Declaration of Independence, and himself in the other. He wound up his discourse by throwing one of the text-books on the floor and trampling it underfoot. The gentleman by whose single vote the proposal was eventually negatived "believed that what was would be anyhow," but said that he would have to discard his religion and vote "No." Why his declared belief should necessitate such a renunciation does not seem to have been stated.

It is unfortunately impossible not to take these exhibitions of irrationality seriously. If they concerned merely the proceedings of a debating society they might be passed over with a smile, but what is here involved is the whole scheme of education in an important section of a great community. It is nothing less than a shock to civilised opinion to find that half the members of a State legislature are oblivious of the fact that, in spite of domestic differences as to the methods of evolution, not a single scientific man of any repute doubts the fact of evolution itself. A refusal to recognise evolution as an established principle is equivalent to eliminating from the teaching of the rising generation the whole body of modern science, chemical and physical no less than biological.

A more disastrously retrograde step in education could scarcely be imagined. It is not too much to say that those who would forbid the teaching of evolution

on religious grounds are doing their best to discredit the religion they profess. We cannot believe that sane opinion in any civilised country would regard the success of such a proposal with anything but the strongest disapproval, and would not heartily commend the utterance of one of the Kentucky representatives who said in the course of the discussion, "I am ashamed of this day in the Kentucky Legislature." If the proposal which was defeated by so narrow a margin had been carried, it would have meant that the State of Kentucky chose deliberately to stand aside from the stream of modern progress, and was content in scientific matters to revert to the intellectual conditions of the dark ages. Some excuse may possibly be alleged for the attitude of the authorities of the time towards the discoveries of Galileo, and even for the distrust with which the work of the early geologists and of Darwin himself was generally received. No such palliation can be pleaded to-day, but the astonishing fact remains that Mr. Rudyard Kipling's imaginary "Village that voted that the Earth was Flat" has been all but paralleled by a State of the American Union.

It would be well if this outburst were a solitary instance of the absurdities that may result from placing the decision of important educational questions in the hands of those entirely incompetent to deal with them. But it is unfortunately the case that the same, or a similar spirit of ignorant intolerance has manifested itself in other quarters besides Kentucky. In the State of South Carolina, a provision has passed the Senate, apparently without opposition, to the effect that "no moneys appropriated for public education or for the maintenance and support of state-supported institutions shall be used or paid to any such school or institution teaching, or permitting to be taught, as a creed to be followed, the cult known as 'Darwinism.'" It is true that this provision was ultimately rejected by the action of a joint committee of the House and Senate, but it is said that another attempt will probably be made to pass it on a future occasion. In explanation of the somewhat curious wording of the proposal, it was stated by its promoter that it was intended to apply only to Darwinism, and not to the theories of Lamarck, Bergson, Le Dantec, Baldwin, or Osborn; further, that it only attempted to penalise Darwinism when taught or permitted to be taught "as a creed to be followed."

It is, of course, true that many convinced evolutionists cannot properly be described as Darwinians; but even if Darwinism, defined as the theory of the origin of species by natural selection, were far more generally discredited among evolutionists than is actually the case, there would seem to be no reason for making a special exception in its disfavour, while allowing teachers to inculcate any of the theories of Lamarck, Bergson and the rest "as creeds to be followed." Whatever may be the ultimate fate of the Darwinian theory, which it is not our present purpose to discuss, it will remain in history, as a recent writer has said, "as the working hypothesis which has led to the establishment of the fact of organic evolution." The attempt, on any ground, to exclude the broad doctrine of evolution or an adequate presentation of the Darwinian theory from the education of the young, is a piece of folly comparable only to the futile endeavour of Mrs. Partington with her mop to stay the advance of the Atlantic Ocean.

F. A. D.

Endocrines in Excelsis.

The Glands Regulating Personality: A Study of the Glands of Internal Secretion in Relation to the Types of Human Nature. By Dr. L. Berman. Pp. vi + 300. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1921.) 18*s.* net.

AS we watch the progress of history as unfolded by the daily press we often find it hard to say whether the event just brought under our notice is an affair of John Smith being sold up because he has failed to pay his rates —a merely local matter—or one of a John Hampden being distrained on account of ship-money—an event destined to be wide reaching in its effects. It is so in the progress of science; of this one is forcibly reminded in the chapters of this book, wherein its author, Dr. Louis Berman, traces the rise and progress of our knowledge regarding the action of internal secretions on the growth, health, and behaviour of the animal body. He duly notes that in the eighteenth century Bordeu of Paris explained the effects of castration on a theory of internal secretions, and he might also have recorded the results of John Hunter's experiments in transplanting the genital glands as well as the spurs of cocks and hens. He notes the very decisive experiments made on cocks by Berthold of Göttingen in 1849. He gives Dr. Thomas Addison full credit for showing, in 1856, that disease of the adrenals was followed by definite changes in the human body. Brown-Séquard has full justice done to him; in 1889, at the age of 73, it is related how he put his theory of internal secretions to the test of practice by seeking for rejuvenescence of his body and brain by the help of testicular extracts. By pooling the experience of Gull, Ord, Kocher, Reverdin, Schiff, and Horsley, the late Sir Felix Semon, as our author notes, was able in 1888 to convince medical men that the ductless thyroid gland had a most potent action on the health and appearance of the body.

That the pituitary gland has an influence on the

growth and moulding of the body became apparent after Marie recognised the disorder which he named acromegaly in 1886. Following these events, Dr. Berman duly notes the discoveries relating to the action of substances formed in the adrenal and pituitary glands by Sir E. Sharpey Schafer, described by our author as "Schaefer, the Scotch physiologist, who has done more than any other living man to stimulate study of the internal secretions." Then follows a mere mention, as if it were a mere minor or parochial event, of the discovery announced by Bayliss and Starling in the Proceedings of the Royal Society for 1904, namely, that the pancreas was set into action by a substance which, formed in the mucous membrane of the duodenum, is carried by the circulating blood to the site of its action.

For Dr. Berman the discovery made by Bayliss and Starling was but a parochial affair of John Smith; for the writer of this notice it is the John Hampden episode leading to a revolution which is transforming the whole field of biology. One has only to turn to the Croonian Lecture given by Prof. Starling at the Royal College of Physicians in 1905 to realise that he was under no delusion as to the revolutionary effect of the discovery of the "hormone" which he named "secretin." He realised that the discovery had revealed Nature's most ancient mode of co-ordinating the action of living units; that a new and potent factor had been placed in the hands, not only of physiologists but also of every man or woman who was working at any department or aspect of living matter—one which gave them a working theory to explain myriads of obscure phenomena. It was the merit of Dr. J. T. Cunningham to apply the new theory to heredity and evolution.

The hormone theory as propounded by Starling in 1905 has had an effect on all branches of medicine—in surgery, medicine, obstetrics, and particularly on psychology. For many thousand years, men of nearly all countries have realised that the removal of the genital glands produces a profound change in the nature and behaviour of all kinds of domesticated animals. The ancient Egyptians must have been aware of these effects. It is the intricate and multitudinous action of hormones on the nervous system which has enlisted the particular enthusiasm of Dr. Louis Berman. In this book he has set out in full detail not only all that can be said in sobriety relating to the *rôle* of internal secretions in regulating behaviour and temperament, but also a great deal which may be true but at present is entirely imaginary. It is with no hint of disrespect that the reviewer suggests that, after all, the unnumbered myriads of nerve cells which make up the brain have something to do with behaviour and personality; the qualities of a man or woman are not determined by internal secretions alone.

The thesis maintained by the author is best given in his own words (p. 23):

"The life of every individual, normal or abnormal, his physical appearance, and his psychic traits, are dominated largely by his internal secretions. All normal, as well as abnormal individuals are classifiable according to the internal secretions which rule in their make-up. Individuals, families, nations and races show definite internal secretion traits, which stamp them with the quality of difference. The internal secretion formula of an individual may, in the future, constitute his measurement which will place him accurately in the social system."

In the latter chapters of this work Dr. Berman proceeds to explain, on an endocrine formula, great or uncommon figures in history such as Napoleon, Cæsar, Florence Nightingale, Darwin, Nietzsche, and Oscar Wilde. No doubt there is much to be said for many of his contentions, but when we find Napoleon classed as a "pituitary centred, ante-pituitary superior, post-pituitary inferior, with an instability of both, that would lead to his final degeneration," we have to own that the ordinary historian is not likely to find endocrinology as here presented really helpful to him.

We should not do Dr. Berman and his book justice unless we mentioned the vigour of his style. Every sentence has a "punch" in it—indeed the reader often longs for a plain statement of fact. It is a book which compels one to think as well as to criticise.

A. KEITH.

Positive Rays.

Rays of Positive Electricity and their Application to Chemical Analyses. By Sir J. J. Thomson. (Monographs on Physics.) Second edition. Pp. x + 237 + ix pl. (London: Longmans, Green and Co., 1921.) 16*s.* net.

ALL physicists and chemists, with many who, though less directly, are yet no less deeply interested in the subjects opened up by the study of the phenomena of the discharge tube, will rejoice that Sir J. J. Thomson has found time, amid his many preoccupations, to bring out this second edition of his well-known monograph on rays of positive electricity. The output of scientific work is now so enormous that it is difficult to keep pace with it even in one's own special line of study. It would be practically impossible, if it were not for the assistance given by books such as this, ever to come abreast once more of a subject in which one has once fallen behind. In writing this clear and authoritative account of the

present state of a subject which he has done so much to develop, Sir J. J. Thomson has performed a real service to science.

Although the intervention of the war delayed for some time the fulfilment of the prophecy made by the author in his preface to the first edition, that the method of positive rays would be of service in connection with important chemical problems, it has since been so signally verified that the scientific world has been shaken, and the distant reverberations have re-echoed even through the columns of the daily press. The discovery, made by means of the positive rays, that the chemical elements are in many cases mixtures of substances of almost identical properties but of different atomic weights is, indeed, one which may well justify the distinguished author of the method of positive ray analysis in his conviction "that as yet we are only at the beginning of a harvest of results which will elucidate the process of chemical combination, and thus bridge over the most serious gap which at present exists between physics and chemistry." In addition, however, to advances of which no one could be completely ignorant, many of us were aware that a considerable volume of research of a less startling, but not necessarily less important, character had accumulated in the eight years which have elapsed since the publication of the first edition of "Rays of Positive Electricity," and will welcome this well-balanced account of the present state of the subject as a whole.

The growth of the subject is indicated by the size of the present volume, which is almost twice that of its predecessor. So much has been added to the text and so many sections have been rewritten, that although here and there a critical reader may detect, by some imperfectly concealed join, that a portion of the old text still survives, the book is to all intents and purposes a new production. It cannot be said that the present volume is quite so easy to read as its predecessor. The subject has grown not merely in size, but also in complexity, and all the author's well-known powers of exposition are required, at times, to guide the reader through the very complicated phenomena of the discharge tube. The journey is, however, lightened by the skill with which the author succeeds in visualising the most abstruse physical phenomena, and is illuminated by the frequent flashes in which, rising from the particular to the general, he links the happenings in his discharge tube with some of the outstanding problems of physics and chemistry. Thus new light is thrown, not only on such problems as the disintegration of metals and the production and absorption of gases in the discharge tube itself, but also on the origin of spectra, the mechanism of ionisation, the varieties of chemical combination, and the structure of atoms and molecules.

An interesting account is given of the various methods which have been evolved for producing and measuring the positive rays, including, of course, the mass-spectrograph employed by Dr. Aston for the investigation of isotopes. It is thus possible to compare the relative advantages and limitations of the different methods. The excellent plates at the end of the volume leave little doubt that, when accurate measurements of the masses of the particles are required, the much greater dispersion which the mass-spectrograph makes possible gives it undoubted advantages over other methods. It is, however, not adapted for the investigation of the intricate phenomena of the discharge itself, and it is mainly to the latter problem that Sir J. J. Thomson has devoted his own researches. The reproduction of some of the author's more recent photographs shows the considerable advance which has been made in the technique of the experiments, while new methods of measuring the plates, indicated in the text, add greatly to the accuracy of the measurements.

In addition to the now well-known parabolas, the author directs particular attention to the existence of numerous other secondary lines of very varied appearance and to the remarkable variations in brightness or "beading" seen on many of the parabolas in the photographs. Considerable space is given to the elucidation of these appearances, and from them the author derives, not only many practical hints for eliminating some of the ambiguities which previously existed as to the nature of the particles to which a given line on the plate must be ascribed, but also much interesting and valuable information as to the processes going on in the discharge tube itself and the mechanism by which the positive rays are produced. It is impossible to pursue the argument in a review, but it forms by no means the least interesting part of the work.

In one respect we fear that the author may unintentionally be misleading his readers, and that is in the statement that the technique of the subject is not difficult. Here we feel that Sir J. J. Thomson is, unconsciously, undervaluing the very exceptional experimental skill which he and his able assistants have shown in this prolonged and difficult series of researches. In particular the electrical method of measuring the rays, which alone seems capable of giving those metrical results which are so desirable for the solution of many of the outstanding problems, has not until the last few months found any successful exponent since the original experiments of the author himself. We can, however, cordially agree that any

chemist with the necessary scientific insight, who would take the time and pains required to become master of the method, would find in it a weapon of research of no mean value.

Some misprints, one or two of which may at first sight rather puzzle the reader, occur. The collection of the whole of the plates at the end of the volume is a great convenience, as the same plate is frequently referred to in different parts of the text. One suggestion we should like to offer in this connection, and that is that the author should provide some key to these very beautiful reproductions of his photographs. It is sometimes extremely difficult for one not versed in the art of reading positive ray photographs to pick out the particular lines referred to in the text from the considerable number which often appear on the corresponding plate. We hope that Sir J. J. Thomson may be prevailed upon to make this concession to human weakness when, at some date which cannot be very far distant, he makes a further revision of the book for its next edition.

J. A. C.

Metamorphoses of Insects.

Insect Transformation. By Prof. G. H. Carpenter. Pp. xi + 282 + 4 plates. (London: Methuen and Co., Ltd., 1921.) 12*s.* 6*d.* net.

METAMORPHOSIS in the animal kingdom may be approached from two angles of vision. We may regard it solely as a preparation for the adult condition that follows upon it, or we may consider it from the point of view of recapitulation of racial ancestry. In reality it is the result of the working of both those factors. Among insects, the higher one ascends among the orders of that class, the more the evidence of recapitulation becomes obscured by secondary changes. Divergence in evolution has occurred between the preparatory and final stages of life. The more highly specialised the perfect insects become the more their larvæ degenerate. It is the inert, legless, eyeless, and often headless maggot that gives rise to the highest expression of insect life. The active "intelligent" type of larva, endowed with limbs and well-developed organs of special sense, is destined to produce an imago lower in the scale of evolution than that which arises from the degenerate larva previously mentioned.

In the springtails there is no metamorphosis. In the locust and the plant-bug metamorphosis is clearly evident, although the young are not very different from their parents. Such insects pass through no pupal stage, and their wings are formed externally. In the majority of insects, however, whether they be beetles, butterflies, bees, or flies, the young or larvæ are vastly different from their parents and a pupal stage has become intercalated in the ontogeny. In insects of this kind the wings arise as impushed imaginal buds and reveal themselves outwardly only when the pupal stage is assumed.

In Prof. Carpenter's book we have a lucid account of the various aspects of the above phenomena. It is elementary, but not unduly so, and there are few biologists who will not benefit by assimilating its contents. The author devotes about two dozen pages to describing the essential features of the morphology of an adult insect. These pages contain nothing that is new to the entomologist, but they enable the more general reader to obtain a better understanding of the book as a whole. The following chapter is devoted to the discussion of the metamorphoses of insects with the open type of wing-growth. This is succeeded by a detailed treatment of the higher orders of insects the wings of which develop from concealed imaginal buds. The remaining chapters treat of wingless insects, the significance of metamorphosis in classification, the surroundings of developing insects, and the various problems of metamorphosis.

The author has marshalled his facts into a continuous whole with conspicuous success. He leads the reader, step by step, through the increasing complexities of metamorphosis in what we believe to be their true evolutionary sequence. He attempts no new theories nor does he throw fresh light on existing theories. He prefers to draw extensively upon the results of recent research and show them in their true perspective. The book consequently represents very completely the present-day point of view. The discussion of larval and nymphal stages naturally occupies a large part of a work of this nature. Prof. Carpenter evidently does not concur with Comstock in his use of the term nymph, and rather adopts the definition that applies it to all exopterygote insects when the latter are in a stage in which the wing rudiments can be distinguished clearly by the naked eye. The expression nymph, however, is a conventional one, and in reality all nymphs are, in the zoological sense, larvae.

The book is one which imparts a true appreciation of how the details of the life-histories of different types throw light on the development of insects as a class. It is well printed and adequately illustrated with figures largely borrowed from the writings of contemporaries, or from Prof. Carpenter's own publications. Few scientific works have been issued since the war at so reasonable a price, which is a matter for congratulation to the author and publishers alike.

A. D. IMMS.

Chemical Disinfection and Sterilisation.

Chemical Disinfection and Sterilisation. By Dr. Samuel Rideal and Dr. Eric K. Rideal. Pp. vii+313. (London: Edward Arnold and Co., 1921.) 21*s.* net.

IN the year 1909 the third and last edition of "Disinfection and the Preservation of Food" was issued. It was a well-known and valuable work written by Dr. S. Rideal, and the many who consulted it will be struck, after perusing the volume under review, with the similarity between the two publications. The new title "Chemical Disinfection and Sterilisation" is a little misleading—for the methods of disinfection described are not always chemical, and the authors have much to say upon the subject of antiseptics, which is neither "disinfection" nor "sterilisation."

There is no one in this country better qualified to treat of the general subject of disinfection than Dr. S. Rideal, so those who consult this book for information on the science and art of disinfection may do so with confidence. But often there will be felt some regret that the information is not more detailed, although the following extract from the preface disarms criticism under this head. "Some apology is needed for the method of presentation. Although some of the problems which are briefly discussed are already dealt with *in extenso* in a wide and varied literature, others, equally important in their respective fields, are scarcely mentioned in current text-books, and it was felt that the inclusion of even a brief summary between the covers of one volume would appeal to those whose interests cover this wide field, but who have neither access to, nor leisure to study, the very scattered literature on the subject." A valuable feature of the work is the bibliographical information at the end of each chapter, supplemented by many useful footnotes.

Chapter 1 is introductory and contains some interesting historical references. Here the statement that "cats and dogs have been shown to carry Diphtheria" is open to challenge. Chapter 2 deals with the disinfection of air; the reference here to the employment of formic aldehyde vapour is particularly good. In chapter 3 the sterilisation and preservation of food is discussed. The inclusion here of the subject of metallic contamination seems inappropriate; and the poisonous products of decomposition, the chemical preservatives employed, and the pasteurisation of milk are far too lightly touched upon. Chapter 4, upon the sterilisation of water, is perhaps the best and most helpful chapter in the book and the authors are to be congratulated upon an excellent and up-to-date statement. Chapter 5 deals with public disinfection. The field is comprehensively surveyed, but the survey is not detailed enough in many parts. For example, the dozen lines devoted to the practical disinfection of excreta are inadequate for the purpose of dealing with this important and difficult subject. Chapter 6, dealing with personal and internal disinfection, contains much useful information. The reference to disinfectant soaps is very full—fuller perhaps than their value, as disinfectants, under the usual circumstances of their employment, would seem to justify.

Chapter 7, upon non-bacterial parasites (lice, scabies, ringworm, fleas, etc.), is full of useful information. The parasites of the lower animals are also dealt with in this chapter. In chapter 8 the complex and difficult subject of the preservation of wood is appropriately treated, while chapters 9 to 13 deal with the chemicals employed in disinfection. The relationship between chemical and physical constitution and germicidal activity is briefly but clearly treated. Chapter 14 deals with methods of analysis and testing; and the Rideal-Walker evaluation test is of course very fully considered, for it is a method which has become widely adopted.

One sympathises with the decision of the authors to make no special reference to those disinfectants which are proprietary articles, and yet the statement seems incomplete when they are excluded, seeing that some of the best liquid disinfecting agents in practical use come into that category.

Full indices of subjects and authors close a book which, despite certain defects (always of omission), is a useful and authoritative statement upon the subject with which it deals.

Electrical Diagnosis.

The Diagnosing of Troubles in Electrical Machines. By Prof. M. Walker. (Longmans' Electrical Engineering Series.) Pp. xii+450. (London: Longmans, Green and Co., 1921.) 32*s.* net.

WHEN an electrical machine is not working satisfactorily it is necessary for the engineer to diagnose the trouble and, if possible, suggest a remedy. The engineer in the works when testing the finished machine has every scientific instrument at his command. On the other hand the engineer responsible for running machinery has only a few voltmeters, ammeters and wattmeters available. Both engineers, however, will probably find what they require in the book under notice. It would be impossible within the limits of a single book to deal with every case that might arise, but there are several general methods of procedure given by the author which if

followed will so limit the position or nature of the fault that its detection becomes easy. Prof. Miles Walker has had exceptional experience with machinery during the last thirty years and so lays the greatest stress on those faults which occur most often; in some cases the faults are due to abstruse causes which make great demands on the expert's knowledge of physical science.

The subjects are well divided, chapters being devoted to break-down of insulation, over-heating, low efficiency, sparking at the brushes, etc. The method of determining the efficiency of an electric generator by air calorimetry—a method first devised and put into practice by Sir Richard Threlfall—is commended and the various methods of measuring the velocity of the stream of cooling air are described. The author attributes to Kennelly the discovery that the heat convection from a thin wire increases as the square root of the air velocity. It is true that Kennelly discovered this law experimentally, but the complete law had been deduced mathematically from physical principles several years previously by the French mathematician Boussinesq. He also proved theoretically Newton's law of cooling; namely, that the heat convected is proportional to the difference of temperature between the wire and the cooling fluid. This law, generally assumed as obvious by engineers, has been verified in the most satisfactory way by physicists.

In chapter 5 the practical application of vector diagrams is described, but the author does not distinguish clearly between the various kinds of vectors which are in everyday use. He begins by considering the vectors of two alternating functions which do not follow the harmonic law. The cosine of the angle between the two vectors is defined as the ratio of the mean value of their product to the product of the effective or root-mean-square value of each. It is therefore a highly complicated function. It can be shown that in accordance with this definition, when we have three alternating functions, their vectors can be represented by three lines drawn from a point in space. Hence, contrary to what the author says, a knowledge of the angles between the first and third and the second and third vectors does not enable us to give the angle between the first and second. The author then proceeds to describe rotating vectors, but he does not state explicitly that he is now making sine curve assumptions. The diagram representing as vectors the fluctuating part of the electrical power taken from the various mains requires more explanation.

The comments made on balanced loads are of interest, but are not very practical. It seems to the writer that a polyphase load is only balanced when the magnitudes of the volt-amperes taken from each main and the phase differences between the volts and amperes of each main are the same.

In a few cases where the author gives formulæ, as, for instance, the formulæ for eddy current losses, it would be a help to many if the proof were indicated. The limitations also of the formulæ should have been stated. A few new words are introduced. The phrase "wattful load" is used to indicate the power expended on the load. It is complementary to "wattless load," a phrase used almost universally by engineers to denote the magnetising power required by the load. Although many diagrams are given showing ripples in waves, harmonic analysis is barely mentioned. The causes of these ripples, however, are described, and many ingenious remedies are suggested.

The Inner Impulse.

La Forme et le Mouvement: essai de dynamique de la vie. By Georges Bohn. (*Bibliothèque de Culture générale.*) Pp. xii+175. (Paris: Ernst Flammarion, 1921.) 4 fr. 50 net.

THE title leads one to expect a discussion of the effect of movement on the form of animals, perhaps new evidence for Lamarck. Nothing could be further from the author's intention. He seeks to show that the laws regulating the reproduction and growth of living creatures are the same as those which govern their movements, and that these are the laws of chemical physics. The conception of an organism as a whirlpool is at least as old as Cuvier, but remained little more than a useful analogy till F. Houssay superimposed on it the idea of vibration. But for him both the vortex and its vibrations expressed the effect on the creature of its environment. Prof. Bohn starts with molecules of living substance, the inherent vibrations of which produce a system not merely vortical but polarised, manifesting its internal forces through oscillations in space and in time. That sentence, so far as possible in Prof. Bohn's own words, will scarcely be intelligible to one who has not read the book. Nor, we are warned, will perusal of the book profit an inquirer unacquainted with the fundamental ideas of physics and mechanics. It may therefore be due to some gap in our knowledge that we rise from a second reading provoked but puzzled, interested but unconvinced.

It needs no very close acquaintance with modern biological research to realise the importance of chemical constitution. We have learned that every species has a chemical character of its own; we are familiar with the part that catalysers, hormones, and other more hypothetical substances, play or are supposed to play in all the functions of the body, in growth, and in the hereditary transmission of form. The study of

tropisms and other movements of living beings has revealed how greatly these depend on purely physical forces. A mechanistic theory of life may not be correct, but is at least intelligible. Prof. Bohn, however, goes much further than this. He would explain the manifold variety of living form, past, present and future, by physico-chemical processes within the creature, influenced from outside only by corresponding chemical or physical factors acting directly. For selection or adaptation he has no use, holding a structure to be a consequence as inevitable as any precipitate in a laboratory test-tube.

Let us illustrate by two of Prof. Bohn's inferences. Stockard has shown that, in sea-water containing an excess of magnesium chloride, the eggs of the fish Fundulus develop cyclopic young to the extent of 50 per cent. These young are as vigorous as the controls, and swim with equal facility. "This fact shows that the evolution of the eye is effected not only, as the Lamarckians believe, under the influence of light, but that it may depend on a chemical factor." Similarly, the fact that various salts, or excess or deficiency of oxygen, favour or inhibit the growth of wings, leads Prof. Bohn to conclude that the insect fauna of oceanic islands must owe its wingless condition to some chemical agent. Wingless insects cannot well have migrated to, say, Kerguelen, but blind cave animals have, in Prof. Bohn's view, sought the seclusion which a cavern grants because they were already blinded.

Failure to follow such tenuous argument need not preclude a welcome to this little book for its insistence on facts and ideas that should certainly prove fruitful, if not on the precise lines imagined by its author. His conclusions seem to ignore that aspect of the unity of nature which is revealed in the myriad interrelations of living things, the delicate balance of life, and the intimate adjustment of successive generations to the changing surface of the Earth. If Prof. Bohn would lock his laboratory door and spend a year in the open field, he might there be exposed to some influences, which, though not purely chemical or physical, would change his mental attitude.

Economic Aspects of Human Wastage.

Waste in Industry. By the Committee on Elimination of Waste in Industry of the Federated American Engineering Societies. Pp. xii+409. (New York and London: McGraw-Hill Book Co., Ltd., 1921.) 20*s.* net.

BRIEFLY to review this book is an almost impossible task, and the only way to accomplish it at all, while doing justice both to the writers and the public, is to give an indication of its contents and the methods employed, at the same time pointing out the fundamental importance of certain of the problems discussed.

The book is the report of a committee which made a detailed inquiry into certain industries with a view of finding out how waste of human effort occurred, and, so far as possible, to appraise the responsibility for such waste. The first part is a summary of the detailed reports, and may be taken as the general conclusions at which the committee arrived. The second part contains the detailed reports of the investigations into the building, clothing, boot and shoe, printing, metal, and textile trades. The third part contains general reports on such specific problems as unemployment, labour troubles, accidents, industrial hygiene, etc. This arrangement of the matter makes it extremely easy for the reader in search of special information to find what he needs with the least possible trouble. An attempt is made to determine the amount of waste due to inefficient management, want of planning, labour turnover, seasonal fluctuations, accidents, etc., and it is clear that a large proportion of the responsibility is due to management. This is necessarily the case, since any improvement reducing wastage from such causes as labour turnover and accidents must at least be initiated by those who are responsible for the general policy of industry.

A criticism that may be passed upon this work is that its outlook is narrow, for, with the exception of a few sections by medical men, attention is confined almost entirely to the economic aspect of human wastage. This is not really a serious criticism. A new science is growing up in all civilised countries which seeks to investigate the interaction between industrialism and human nature. To this infant science psychologists, physiologists, doctors, statisticians, and engineers are all contributing, and we must not blame any specific piece of work if one particular aspect of the question is somewhat over-emphasised. The very existence of such a science is a confession that these problems can no longer be regarded as the preserves of philanthropy or politics, which have both failed to remove any but the crudest abuses, while many of their endeavours to improve matters have done harm because they have been undertaken without knowledge of the scientific factors involved. For example, unemployment has too often been regarded merely as a problem of insurance, and various schemes have been worked out based upon the arguing power of the parties concerned rather than upon scientifically ascertained facts. Unemployment, as is pointed out in this book, has far wider ramifications, and cannot be treated from one point of view alone. However unemployment occurs, it involves a great national and

international waste, and any system which is concerned primarily with alleviating the suffering entailed rather than removing its cause must be inadequate. By proper planning of work so as to meet seasonal fluctuations, by a wiser use of the competitive system and certain methods of standardisation, much can be done to remove a social evil which is probably doing more to destroy the vital energy of the industrial population than any other one cause.

The book contains a great deal of carefully arranged statistical matter which provides useful data for those wishing to study certain problems independently. Many of the recommendations made are naturally more applicable to American conditions than to British, and it is to be hoped one outcome of the publication of this book will be that a similar inquiry will be undertaken in this country.

Our Bookshelf.

A Text-Book of Inorganic Chemistry. By Prof. A. F. Holleman. Issued in English in co-operation with H. C. Cooper. Sixth English edition, revised. Pp. viii + 528 + 1 plate. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 19*s.* net.

Prof. Holleman's text-book is well known as one of the best introductory treatises on the subject, and it is only necessary to point out that the new edition has been revised and brought up to date. In this operation a few minor inaccuracies have escaped notice. Thus, on p. 133 it is stated that of the nine oxy-acids of sulphur (one is omitted), only sulphuric acid has been obtained in a pure state, whereas on p. 146 the two persulphuric acids are described as crystallising in the pure state. The descriptions of preparations are sometimes so condensed as to be almost inaccurate, *e.g.* (p. 54) hydrogen peroxide "in a very concentrated state can be obtained by direct distillation *in vacuo* of a mixture of sodium peroxide and sulphuric acid," and on p. 69, in connection with the preparation of hydrobromic acid, the usual method is scarcely adequately described as "the decomposition of a bromine compound with a hydrogen compound, phosphorus pentabromide and water being employed." The statement (p. 29) that "the atomic weights of most elements are determined from the composition of their oxygen compounds," although common, is quite incorrect, and should be compared with the true state of affairs, given on p. 306.

Typical Flies: A Photographic Atlas. By E. K. Pearce. Second series. Pp. xiv + 38. (Cambridge: At the University Press, 1921.) 15*s.* net.

The atlas of photographic illustrations of typical British Diptera under notice is supplementary to the one published by the author in 1915. It consists of a series of well-executed half-tone figures arranged on 36 pages. The difficulties experienced in photographing such objects as flies really effectually are considerable. In photographing on the enlarged scale required, no amount of "stopping down" will produce an image sharp all over, since all the parts of an insect do not lie in the same plane. Many of the figures are excellent examples of what can be executed by this method. On the other hand, those of the larvæ and pupæ are not very successful: Fig. 16 of the larvæ of Coretha, for example, is far inferior to a good line drawing. It is difficult, however, to understand why some of the specimens used for illustration were not better chosen. Why, for example, figure a Trypetid fly the abdomen of which is so distorted as to appear to be missing; or, in other cases, utilise specimens in which the legs have never been displayed in the process of setting. We gather the object of this work is to stimulate the study of this neglected but highly important order of insects and, by means of suitable illustrations, to guide the beginner in relegating his specimens to their respective families. In the latter respect this atlas will probably prove of distinct service.

The Yearbook of the Universities of the Empire, 1922. Edited by W. H. Dawson and published for the Universities Bureau of the British Empire. Pp. xv + 653. (London: G. Bell and Sons, Ltd., 1922.) 7*s.* 6*d.* net.

The changes which have been made in this valuable handbook since last year's issue was published are due mainly to an increase in scope and therefore in size. Nearly two hundred pages of useful information have been added, in spite of the fact that the price has been reduced to one-half. Brief accounts are given of the universities, together with lists of their staffs, of England, Wales, Scotland, and Ireland, followed by similar statements for the universities of Canada, Australia, New Zealand, South Africa, India, Malta, and Hong-Kong, in the order given. The appendices, which formed a valuable feature of previous editions, have been extended, so that now most of the learned and professional institutions are dealt with. There are also brief notes on continental universities and universities in the United States of America, as well as information on the subjects of inter-university scholarships and grants for research both at home and abroad. The text is reduced to a minimum, but the essential facts are given, and it is difficult to find any other single volume which will serve so effectively as a reference book on institutions for higher education in the British Empire.

Mémoires sur l'Électromagnétisme et l'Électrodynamique. Par André-Marie Ampère. (Les Maîtres de la Pensée Scientifique: Collection de Mémoires et Ouvrages. Publiée par les soins de Maurice Solovine.) Pp. xiv + 111. (Paris: Gauthier-Villars et Cie, 1921.) 3 francs net.

The two memoirs given in this volume have been taken from Ampère's wonderful "Recueil d'observations électrodynamiques," published in 1822. Œrsted had described a few years previously the action of an electric current on a compass needle, and in the first memoir under notice, the mutual action of two electric currents on one another is described. The author then describes the apparatus he made and the

experiments he carried out. Finally he formulates the laws which we use to-day. In the second memoir the formula for the mutual action between two infinitely small elements of conductors carrying currents is proved. Ampère's researches paved the way for much of Faraday's work, and Clerk Maxwell makes full use of his results in his treatise. Clerk Maxwell well called Ampère the Newton of Electricity. The guiding experiments and the theory seemed to start fully equipped from his brain just as Pallas Athene was born fully armed from the head of Zeus.

Small Talk at Wreyland. By Cecil Torr. Second series. Pp. vi+120. (Cambridge: At the University Press, 1921.) 9*s.* net.

IN his second series of "small talk," Mr. Torr, proceeding on the lines followed in his first volume, has brought together a number of pleasantly written discursive jottings on various matters drawn from his own recollections and from the letters and diaries of his father and grandparents. An antiquarian and a scholar, he writes with a light and pleasant touch on such matters as local lore and history, as well as of events in the larger world. The value of these notes lies in the light they throw on the social habits and customs of the middle of the last century; they deal with those illuminating details which are apt to evade the more formal historian. Interspersed are observations of and reflections on happenings which have befallen Mr. Torr during his travels in the Mediterranean and in Palestine. All topics, whether of a serious or a lighter character, are touched upon in a manner which can only be described as urbane. On one subject alone does Mr. Torr's urbanity desert him, and that is when he is moved to comment upon the Government regulations for the cultivation of the land during the war.

Chemical Reactions and their Equations: A Guide and Reference Book for Students of Chemistry. By Prof. I. W. D. Hackh. Pp. viii+138. (Philadelphia: P. Blakiston's Son and Co., 1921.) 1.75 dollars.

"THE inability to balance a chemical equation is a most common difficulty to students of chemistry." The author has attempted to remedy this very common weakness, and in addition to a concise explanation of chemical notation, including difficult cases of oxidation and reduction and ionic reactions, has provided a list of more than four hundred classified and indexed chemical equations. The book should prove a useful companion to degree students. In the list of solubilities "to be memorised" one finds: "BORATES are SOLUBLE," which is not strictly correct, since most borates are insoluble.

The Practical Chemistry of Coal and its Products. By A. E. Findley and R. Wigginton. Pp. 144. (London: Benn Bros., Ltd., 1921.) 12*s.* 6*d.*

THE analysis of coal, coke, ammonia liquor and ammonium sulphate, tar and its distillation products, gas (including calorimetry), pyrometry, and water analysis, are the topics dealt with in this book. The volume is very attractively printed and illustrated and should prove most useful in works laboratories.

Letters to the Editor.

Definition, Resolving Power, and Accuracy.

IN scientific writings the term "definition" most often refers to the clearness with which details are shown by optical instruments; but by a convenient generalisation it might be taken to mean the ratio of the greatest to the least quantity which any kind of apparatus can render apparent at the same time, being thus distinguished from "sensitiveness" or "resolving power," which is determined simply by the smallest quantity measurable without reference to the size of the field.

In this sense the question of "definition" enters into every kind of measurement. In telescopes and microscopes, for example, it would denote the angular or linear size of the field of view compared with the smallest corresponding quantity which can be clearly distinguished; or, in a balance, the greatest arc through which it can swing compared to the least angle of swing giving a trustworthy measure of change of weight.

Since all measurements have in the end to be recorded by the senses either of sight, hearing, or touch (smell and taste have not yet been examined quantitatively), it is of interest to inquire what kind of definition can be expected in their case, and the following notes contain some of the results of various observations on the subject made at intervals during many years.

Sight and hearing are both dependent on wave-motion, and the sensations produced vary with the intensity, frequency, direction, and duration of the waves. The total range of sensible intensities is enormous; for it is seldom that a night is so dark, or a silence so complete, that absolutely nothing can be seen or heard, yet the eye can work without injury in bright sunlight, and the ear can hear with such noises as thunder or great explosions. In these cases the ratio of the greatest to the least appreciable intensity must be of the order of millions.

Although, however, the perceptions of intensities have such wide limits, the differences which can be recognised at any one time or in any constant conditions are much more limited.

In many respects the senses may be compared with a musical instrument which, while of restricted compass, can be tuned to almost any absolute pitch, so that though for any one tuning comparatively few notes can be sounded, yet by adjustment these notes may take any desired position in the audible scale. Each sense, in fact, seems to adjust itself to some kind of level suitable to its surroundings, and to be able (so far as my own observations go) to discern differences of from 5 to ½ per cent. of the range then appreciable.

The same order of definition was found not only for each sense but also for the co-ordination of the senses with muscular action.

The following experiment on the greatest difference between the intensities of light which can be perceived at the same time always gave fairly consistent results. A long tube AB, Fig. 1, about two inches in diameter, and well blackened inside, was provided with a white paper flange at A, and a movable piston, C, also covered with white paper. A disc of white paper, D, of rather less diameter than the tube was placed at

a short distance from the flange, and could be illuminated by sunlight or other means. A small hole in the disc allowed the eye to look in the direction of the axis of the tube, and when the piston was

FIG. 1.

flush with the flange the view obtained was of a uniformly white surface lit by the light scattered from D.

The experiment consisted in withdrawing the piston until it became invisible, the relative intensities of the illumination of the flange or piston face then being DC^2/DA^2. For sunlight the ratio was about 220 to 230 and for candle-light about 170, thus indicating a definition 0·45 and 0·5 in each case.

Analogous experiments were tried on sound by the use of two lever clocks placed at some distance apart. The distance was then noted at which the ear had to be placed from each in order that one set of "ticks" might be drowned by the other. Musical sounds of the same pitch and loudness were tried in the same way. It is always difficult to make in-door experiments on sound on account of the echoes from walls and furniture, but on the whole it appears that the definition for the intensity of sound was not so good, though of the same order, as for light.

As regards the definition for wave-length, that is, the recognition of colour and pitch, the range for visible light waves is much narrower than that for sound. The lengths of all the visible rays lie within the ratio of two to one, while in sound a compass of more than ten octaves is audible. Few people when viewing the whole spectrum at once will distinguish more than seven or perhaps eight colours, but when only a small portion covers the visible field, the variations of tint are much more marked. I have been told by one well-known observer that he could distinguish between the yellows a very short distance on either side of the D lines. This would correspond to a difference of wave-length of five or six parts in a thousand, but since wave-lengths at the orange and green end of the yellow do not differ by more than a hundred parts in a thousand, the definition implied is not better than five per cent.

Few ears are so unmusical as not to be able to distinguish intervals of a semitone (wave-length ratio about ten per cent.), but fewer still can at once distinguish between a major and minor semitone (about one per cent.), and even fewer between the true semitones and their equal temperament substitute.

The sensibility of the ear to change of pitch varies largely in different parts of the audible range, and is at its best in the two octaves above and the octave below the middle C.

In both light and sound the judgment is improved if there is a fixed standard for reference. No standard would be required by the normal eye to determine whether an object was red, yellow, or blue, but doubt might easily be felt as to the exact shade of the colour if the objects were seen separately at considerable intervals of time, and the longer the interval the less as a rule is the judgment to be trusted.

The relation of musical notes sounded in succession in the same way is less correctly estimated when the time intervals between them are long than when they are short, except for those who have the sense of absolute pitch. I have no good data as to the range over which this rather rare sense extends, but have reason to believe that in some cases and in the vocal compass it is accurate to within one per cent.

The same sort of memory which enables a definite colour or pitch to be recognised without any external standard of comparison is requisite also for the mental division of intervals of space or time. I have known people who could mark off inches and count seconds by memory with errors of not much more than one per cent., but they could not deal with feet or minutes with anything like the same accuracy.

In estimating fractions of a second a good transit observer will approach a two per cent. standard, but whether the second is the best time interval for mental division may be questioned.

As regards the division of space by estimation I may mention the following simple experiment which I have often repeated at intervals of years and always with the same result.

On a sheet of ruled foolscap draw two straight lines intersecting near one end of the sheet, and about six inches apart at the other (Fig. 2). Mark the inter-

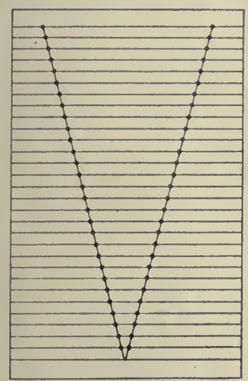

FIG. 2.

sections of these lines with the ruling by well-defined circular black spots, and from another sheet cut out a slot about six and a half inches long and half an inch wide. This when superposed on the first will allow one pair of spots to be visible at the same time. Now, always keeping the eye at the same distance from the paper, mark in succession the point estimated to be midway between each pair. These marks should all lie on the bisector of the angle between the first drawn divergent lines.

In all my trials I found that so long as the subtense of the pair of spots was small enough to allow of both being seen clearly at the same time, the angular error in the estimation of the bisection was more or less constant and ranged from 1/500 to 1/1000 (*i.e.* from $\frac{1}{50}$ to $\frac{1}{100}$ inch at ten inches, the distance of the eye from the paper). The error, however, increased rapidly when the spots were so far apart that they had to be viewed in succession. This occurred when their subtense was about 20°, and the best bisections were made with a subtense of 15° to 12°.

For smaller angles the definition was not so good, for though the linear error on the paper did not change much, it had to be compared with the smaller distance between the spots. In my own case, for angles greater than 20° the error in the bisection was always to the left, but this probably is a personal matter.

As for space, so for time, there must be some particular interval which is best suited for division of estimation, and my impression is that this is somewhat, but not much, longer than a second. As an example of the importance of the correct estimation

of the bisection of a space, I may refer to the results of the recent eclipse expedition which were supposed to confirm Einstein's theory regarding the effect of gravity on light.

According to the account given in the Report (Phil. Trans. A, vol. 220) only one of the sets of eclipse photographs was quite satisfactory, and this was taken by a 4-inch object glass having a focal length of 19 ft. At this distance one-thousandth of an inch would subtend one second of arc nearly, and a 4-inch lens would be just sufficient to separate objects this distance apart. Thus if the lens and photographic plate were perfect, the image of a star would be represented by a circular spot 0·001 in diameter surrounded by one or perhaps two faint rings. In the actual negatives, from irradiation and other causes, the star images were easily visible to the naked eye, and were (speaking from inspection only) about a hundredth of an inch across.

The object of the photograph was to determine the position of the stars to within a small fraction of 1″, so that 10 per cent. in the estimate of the bisection of the 0·01 inch image would represent an angular error several times as great as the whole deviation of the ray suggested by the theory.

The image of a star on a gelatine plate is not a sharply defined disc, but a group of dots crowded together towards the centre but more sparsely scattered round the circumference. This is illustrated by Fig. 3, which is the enlargement (×300) of the

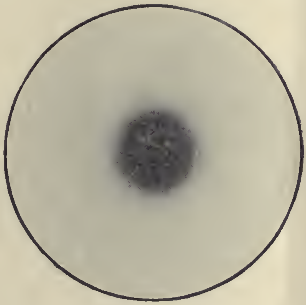

FIG. 3.

direct contact print on a slow "Imperial" plate of a hole 0·0015 in diameter pierced through thin copper foil, and is therefore probably rather more sharply defined than an image formed by a lens.

Thus the evidence for Einstein's theory (so far as the eclipse results are concerned) turns on the question of how much closer than ten per cent. can the bisection of such an area as the figure shows be estimated by the eye.

What magnification was used in the measuring apparatus is not stated in the Report, but assuming that it was between 20 and 40, Fig. 3 would have to be held between 25 and 50 inches from the eye in order that it should appear of the same size as the star image would in the measuring microscope.

Another matter of some interest is the acuteness with which the senses perceive vertical or horizontal acceleration, or in other words the variation of the intensity and direction of the forces acting on the body.

In the inquiry into the vibrations caused by trains in the London Tube Railways, it was found that residents in the neighbourhood began to complain when the vertical movements at the rate of 15 per second amounted to so little as one-thousandth of an inch (amplitude 0·0005), corresponding to a maximum acceleration of $g/12$, but that much smaller accelerations could be felt. Up to a frequency of 40 per sec. or thereabouts, the quicker the vibration the smaller was the amplitude which was perceptible. With frequencies sufficient to give rise to an audible note, the character of the sensation gradually changed.

Church towers rock when the bells are rung, and on one tower rather celebrated in this respect I measured the maximum horizontal amplitude of $\frac{1}{12}$ of an inch, the frequency being rather less than 3 per second. The maximum acceleration in this case also was about $g/12$ and produced feelings of sea-sickness in many people. Accelerations of less than a tenth of this amount, however, were quite noticeable.

I have no notes on the effects of vibrations of long period, but I should expect that any periodic motion which involved an acceleration of $g/200$ would not pass unnoticed, if the conditions were favourable and the attention directed to the subject.

The following are a few examples of the accuracy with which the senses can direct muscular action. In match-rifle shooting sequences of 100 bulls'-eyes (24 inches) at 1000 yards are not unknown. In this case the symmetry of the sight and the target are an assistance in aiming, and since part at any rate of the deviations of the shots are due to wind, etc., the actual alignment of the sights cannot be much greater than 1 in 4000.

By the assistance of a champion billiard player I found that, in playing at a ball under the cushion from balk, he seldom missed the centre aimed at by more than $\frac{1}{8}$ inch. This is equivalent to an accuracy of 1 in 1000. The trials were made by using a paper disc, backed with carbon-tissue and a hard wood support, as the target, the disc being of the same diameter as a billiard ball. The point of impact was shown by the black dot left by the carbon on the reverse side.

A good bowler can generally hit a single stump at 22 yards. A cricket ball has, I believe, a diameter of $2\frac{5}{8}$ inches, so that taking the thickness of the stump into account the accuracy in this case is about 1 in 380.

As regards archery, the best of modern archers[1] will scarcely keep his arrows within a 3-ft. circle at 100 yards. If he did the accuracy would be 1 in 200.

For a game-shot who can bring down 75 per cent. of his birds at 40 yards, the implied accuracy of aim is about 1 in 70.

In all these cases the attention is concentrated on a field of only a few degrees, and the effect of the restriction of the field on the accuracy of the estimation of the position of objects within it is worthy of more investigation than it has yet received.

In judging the qualities of the instrument with which measures are made, a distinction should be drawn between accuracy or resolving power and definition. The accuracy with which a weight can be determined by a balance, or a resistance by a Wheatstone bridge, is greater than one part in a million, but the definition is, for the balance, the length of the arc in which it can swing compared to the least angular motion which gives a trustworthy indication, and, for the bridge, the length of the resistance wire on which contact is made compared with the least variation of the position of contact

[1] How old is the legend of the pole, string, and bird, as a test of an archer's skill? Tom Sawyer, it may be remembered, improved on this, saying that Robin Hood "would take his yew bow and plug a ten cent piece every time—mile and a half." In Joshua xx. 16 there is a reference to seven hundred left-handed men of Benjamin. "Every man could sling stones at a hair's-breadth and not miss." This, I think, is the only Biblical reference to accuracy of marksmanship.

which can be shown with certainty on the galvanometer. Accuracy will depend, among other things, on the accuracy of the weights and balancing resistances employed, while the definition is decided by the workmanship and design of the instrument alone.

In optical instruments, resolving power is judged by the smallest angular or linear quantities which can be distinguished by their means, and definition by the relation which these quantities have to the size of the field over which they are distinguishable. If a telescope, for instance, can distinguish seconds of arc, its resolving power is 206,000 nearly, but if the field over which this resolution extends is only half a degree, the definition would be 1800 (*i.e.* $206,000/57 \times 2$).

Although the performance of any combination of real lenses depends on design and workmanship, it is not difficult to find the limits beyond which even perfection in both does nothing to increase resolving power.

The function of a perfect lens is to change the radius of curvature of a spherical wave surface.

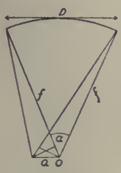

Fig. 4.

Let D (Fig. 4) be the diameter of the lens where the change is effected, f the new radius of curvature, and o the geometrical focus. From every part of the wave surface at D partial waves may be supposed to spread, all of which will reach o in the same phase. Confining the attention for the moment to those rays which start from the opposite ends of a diameter of the lens, the partial waves from either end will be in opposite phases at a distance a, in the focal plane, from o if $2a \sin \alpha/2 = \lambda/2$, where α is the angle subtended at o by D, and λ the wave-length of the light. Also, since $\sin \alpha/2 = D/2f$, $\alpha/f = \lambda/2D$ and $a = f\lambda/2D$. Thus $\lambda/2D$ and $f\lambda/2D$ are the least angular and linear distances from the geometrical focus at which a total absence of light can be found.

If the partial waves are received from the whole marginal annulus of the lens, in place of those from the extremities of a diameter, the value of a_1 is slightly increased, and the image about o of a distant point of light is a bright circular area surrounded by a series of rings. (The rings are caused by recurring coincidence of the phases of the partial waves at certain distances from o greater than a.) The bright centre and rings are identical with those seen in the well-known experiment in which a bright point appears in the centre of the shadow of a disc, illuminated by a bright distant source.

If the whole area of the lens is employed the diameter of the bright centre is further increased, but the intensity of the rings is much reduced. This case, as it applies to telescopes, has been considered by Airey in a paper on "The Intensity of Light in the Neighbourhood of a Caustic," published about the middle of the last century.

In whatever manner, however, the lens is used, whether with a central stop, or with its whole area uncovered, a/f and a are the least angles and distances which separate the geometrical focus from the truly dark boundary of the image, although, owing to the rather rapid diminution of intensity from the centre to the circumference of the image, it is possible to recognise angles smaller than $\lambda/2D$ (this applies to telescopes in which α is always small), or distances less than $\lambda/2$ by the use of microscopic objectives of large angular aperture, where $\sin \alpha/2$ approaches unity.

The appearances presented at the focus when two objects in such close proximity are examined can scarcely be described as the images of the objects, but rather as interference phenomena which require interpretation.

A. Mallock.

9 Baring Crescent, Exeter.

Discoveries in Tropical Medicine.

In Nature of April 29, p. 549, Sir E. Ray Lankester criticises an obituary notice on Sir Patrick Manson which appeared in the *Times* of April 10. The statement chiefly objected to is that "modern tropical medicine was born the day that Manson discovered the part played by the mosquito in the transmission of *Filaria sanguinis hominis*." But all parasitologists know that it was Manson who, forty-four years ago, proved by experiment the part played by mosquitoes in the propagation of filariasis. This discovery is not only the pride of tropical medicine, but the very breath of modern medicine and one of the most glorious achievements of British science.

Strange to say, Sir Ray Lankester to-day repeats, almost word for word, a mistake he published twenty years ago in the *Times*. He says: "The fact is that Manson's 'suggestion' that the Filaria of elephantiasis [*sic*] is actually carried by mosquitoes from the blood of one person to that of another remains to this day a 'suggestion.' It has not been established as a fact."

It is surprising that a naturalist of repute, who writes frequently on matters medical, should make this mistake. Surely Sir Ray Lankester must have come across books on parasitology written within the last twenty or thirty years. How can he say that the agency of the mosquito, in the dissemination of filariasis, has not yet been established? Was it not surmised by the Chinese ages ago? Was it not suggested by Bancroft of Brisbane (Queensland) in 1877? Was it not independently and experimentally proved by Manson, in China, that very same year? Only one thing remained uncertain for some years, and that was the actual method by means of which the young filariæ, after reaching a certain stage of development within the body of their insect host, left the mosquito to invade man; but this was fully established and admirably demonstrated between 1899 and 1900 by Manson, Low, Bancroft, Annet, and Dutton, James, Noè, Grassi, myself, and others. Dr. Low's beautiful celloidin sections of infected mosquitoes showing the worms, either quiescent between the massive thoracic muscles of the insect, or actively migrating to the latter's mouth parts and fixed while passing beneath the cephalic ganglia, gliding down within the labium, or escaping through a rent between the labella, at the distal extremity of the labium, have been exhibited repeatedly, not only at the Royal Society and elsewhere in this country, but also, on several occasions, in France, Italy, and Belgium. Moreover, they have been photographed and even reproduced in colour by skilled artists, and both photographs and drawings have appeared in books on tropical medicine and parasitology published since 1900.

Sir Ray Lankester refers to two other vexing questions, namely, the discovery of the part played by mosquitoes in the propagation of the intermittent fevers and that of tsetse flies in the transmission of certain trypanosome diseases of animals and man such as nagana and sleeping sickness. With regard

to malaria, he says: "The man who actually 'discovered' the fact of the carriage of malaria germs by a mosquito and the particular species (*Anopheles maculipennis*) so concerned, as well as important facts as to the multiplication of the malarial parasite in the gnat's body, is Sir Ronald Ross." This short statement includes several mistakes. In the first place, *Anopheles maculipennis* is not the only anopheline concerned in the transmission of malaria, because several species belonging to the genera Anopheles, Myzomyia, Pyretophorus, Myzorhynchus and Cellia play an active part in the transmission of the intermittent fevers, within their respective habitats. Then again, *Anopheles maculipennis* was unknown to Ross in India for the simple reason that it is not to be found anywhere within the Indian triangle. *Anopheles maculipennis* is a Holarctic species ranging over North America and throughout Europe and extending round the shores of the Mediterranean Sea and its islands, but otherwise absent from both the Oriental and Ethiopian regions.

Sir Ray Lankester states that Prof. Laveran, the discoverer of the malaria parasites of man, had already previously suggested mosquitoes as the carriers of paludism. I can adduce much older evidence to prove that in malarial stations the natives long suspected the mosquito as the probable cause of infection, just as the tick was suspected of being the carrier of relapsing fever and the body louse the vector of typhus, because the name of the dread "Fever-fly" is inscribed in cuneiform characters on a Babylonian clay tablet of thousands of years ago, now preserved in the British Museum. But Sir Ray Lankester ignores Manson's brilliant interpretation of the "flagellating" malarial parasite, looked upon by the Italians as a form of degeneration; by Manson as the prelude to a further all-important developmental stage outside the body of man. He overlooks the fact that Ross's investigations were inspired by Manson, and that Ross was all along instructed, aided, and supported by Manson. I need but quote Ross's own words in the paper he sent to the French Academy of Medicine, January 24, 1899: "*Pour éviter tout commentaire erroné, qu'il me soit permis de déclarer ici que mes travaux ont été entièrement dirigés par Manson, et que j'ai eu l'assistance de ses conseils et de son influence à toute occasion.*" During the whole period of Ross's work in India, I was almost daily at Manson's house, where I had the privilege and good fortune of being able to follow step by step the unfolding of one of the most wonderful chapters of tropical medicine. I was allowed to read the correspondence, examine the specimens sent by Ross to Manson, and discuss every detail. I do not wish to minimise in any way the importance of Ross's work. Humanity and science are greatly indebted to Ross for his splendid researches and no one appreciated this more than Manson, but all the world knows that Manson was the man at the helm; Ross himself has stated it quite frankly and honourably in his writings.

It was Manson who first clearly grasped the problem, it was Manson who planned the *modus operandi*, it was Manson who chose the man who should carry out his ideas and do the work, and, when failure threatened, as in the case of the Italians, when *they* attempted to solve the problem, it was again Manson who saved the situation, by suggesting that the researches be continued with the Plasmodium parasites of passerine birds. Indeed, the life cycle studied and unravelled by Ross was that of *Plasmodium danilewskyi*, a blood parasite of sparrows and not that of any of the malarial parasites of man. It was in Italy, by Profs. Grassi, Bignami, and Bastianelli, that it was actually proved that the malaria parasites of man go through exactly similar transformations and migrations as those of *Plasmodium danilewskyi*; not, however, in any of the Culicinæ, as Ross had proved for the bird parasites, but in a different subfamily of mosquitoes, the Anophelinæ. Finally, the experiments carried out by Manson in London and by Dr. Low and myself in the Roman Campagna, in 1900, put the last brick in the structure of proof and were especially important in proving that, under natural conditions, the intermittent fevers cannot be contracted in any other way than through the stab of Anopheline mosquitoes. However, it is only right to say that Ross's experiments were undertaken at Manson's request, for the sole purpose of elucidating the etiology of human malaria, that Ross began by using the plasmodium parasites of man, and that the first mosquitoes he infected and examined were "dappled-winged" mosquitoes, that is to say, in all probability, Anopheline mosquitoes. Great discoveries are seldom made by a single man. Ross would never have done this work had he not come across Manson, and probably Manson might have had long to wait for the establishment of his theory had he not found Ross.

With regard to sleeping sickness, Sir Ray Lankester is no better informed. Sir David Bruce did certainly prove that "nagana," the horse disease of Africa, is caused by the same kind of parasite—a trypanosome—discovered by Evans, eleven years previously, in "surra," the horse disease of India, and he repeated very fully the experiments previously made by Dr. David Livingstone and by others to ascertain whether the African natives were right in suspecting the tsetse flies as carriers of the infection, but, unfortunately, Bruce gave wrong interpretations to his own experiments and to those of others, contending that the fly acted merely as a passive carrier, "just as a vaccinating needle"—these are his very words.

It was Prof. Aldo Castellani who first demonstrated the true causative agent of sleeping sickness—a trypanosome which he found not only in the blood, but also, and chiefly, in the cerebro-spinal fluid of sleeping-sickness patients. At the same time, Prof. E. Brumpt of Paris and I, independently, simultaneously, and some months before the publication of Bruce's work, incriminated a tsetse fly as the carrier of sleeping sickness. Prof. Brumpt suggested *Glossina morsitans* as the probable vector, basing his belief partly on Castellani's discovery and partly on his own extended field work in the French Congo. I incriminated the dusky tsetse fly (*Glossina palpalis*), basing my opinion on a careful study of the peculiar topographical distribution and other striking epidemiological features of the disease, on analogy with the better known epidemiology of nagana, and on the bionomics and distribution of the then known species of tsetse flies. At the International Conference on Sleeping Sickness (London, 1907) and at several meetings of the British Medical Association, I endeavoured to prove that the "sexual" dimorphism noticed first by me in the trypanosomes of sleeping sickness (specimens forwarded by Dr. Low to the School of Tropical Medicine) and a critical study of Bruce's experiments on both nagana and sleeping sickness showed that the respective trypanosomes go through a necessary cycle of development (sporogony) within the body of their definitive insect-hosts, analogous to that of malaria parasites in the body of mosquitoes. Six years later (1909) Klein's careful researches in Africa fully proved the justice of my interpretations.

LOUIS W. SAMBON.

The Blue Flame produced by Common Salt on a Coal Fire.

IT is sometimes stated that the blue flame which is seen when common salt is thrown on to a coal fire is due to traces of copper in the coal. It is much more likely that this flame is that of carbon monoxide produced by the cooling of the hot coal by the salt, and certain observations lend support to this view, such as the following:

(1) The blue flame is visible under proper conditions without the addition of salt (and is commonly held to portend frosty weather).

(2) The addition of salt to a fire consisting of white-hot embers—that is, one from which most of the carbon has been burnt—gives no blue flame, which it should do if the flame is due to copper chloride.

(3) The addition of other substances than sodium chloride produces the same effect, a spent filter paper for example.

(4) The colour of the flame seen is apparently identical with that of the carbon monoxide flame but not with the green copper colour.

(5) The sodium flame is never observed in this case because the temperature is too low to volatilise the sodium chloride. For a similar reason it is unlikely that the copper flame can be observed.

Possibly I am wrong, but the matter is interesting, and deserves to be made clear. W. HUGHES.

63 Goldington Avenue, Bedford.

MR. HUGHES's letter raises some interesting questions regarding the conditions under which the "blue flame" of the coal fire appears. There is no reason to suppose that under appropriate conditions the flame of burning carbon monoxide cannot be seen in a coal fire, but it would be difficult to identify since the spectrum is, in the main, continuous. On the other hand, the blue flame of copper chloride, which is distinct from the green flame of the oxide, has a very characteristic spectrum, and there is no difficulty in its identification. There is no doubt, however, that for the appearance of the spectrum of a compound certain accessory conditions have to be fulfilled, and in many cases their effect is by no means obvious. Perhaps one of the most striking instances of this is to be found in the appearance of the spectrum associated with burning sulphur in the flame of an ordinary bunsen burner when the gases of the flame are cooled, *e.g.* by holding a thick plate of cold metal in the flame. In this case the sulphur occurs as an impurity in the coal gas but is not seen in the spectrum of the burning gases unless they are cooled. T. R. MERTON.

Winforton House, Hereford.

Pilot Lamps in Laboratories.

TYPES of neon vacuum tubes recently placed on the market as low candle-power glow lamps for household electric lighting circuits, apart from other uses, have several convenient applications in laboratories as indicators to show when the supply current is flowing in any given circuit. These lamps, which are said by the makers to give only ¼ c.p., have a very high resistance and small current consumption: one type tested on a 200-volt circuit took either 3 or 10 milliamperes, according to the polarity of the connections, while another type took 12 and 30 milliamperes under the same conditions, though individual lamps of the same type vary considerably. In each case the lamp behaved well with a resistance of more than 20,000 ohms in series, and a current consumption of less than one milliampere.

In the case of electric furnaces, muffles, etc., one lamp in parallel with the heating winding serves to show when the current is "on," obviating the chance of the apparatus being left under load when the laboratory is closed at night, and effecting obvious economies by indicating the consumption of current at other times. With electrically heated thermostats, incubators, constant temperature ovens, etc., where the means of heating are not directly visible, a neon lamp serves usefully to indicate contact when making adjustments, while the use of a second lamp shunted across the contact breaker reduces arcing and removes any doubt as to the supply of current when the other lamp is out. Fig. 1 shows a simple method of placing the two lamps in such a circuit. H is the heater winding, B the break, L^1 and L^2 the two neon lamps, while R is a high resistance of 20,000 ohms or more, made by drawing pencil lines on a piece of ebonite between two terminals until a satisfactory glow is given by the lamps.

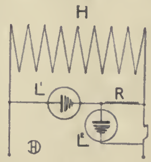

FIG. 1.

The working of such an arrangement is self-explanatory, one of the two lamps always being alight while the current is on. The current consumption on 200 volts is only ⅛th watt—or 5000 hours' service for the cost of one unit.

Where these lamps are required as "pilots" for a large number of circuits, advantage may be taken of the special types designed for advertising purposes, where the electrodes are given the form of letters and other symbols. The makers are prepared to manufacture these in any form if necessary, and such simple words as "on" and "off" could be provided if required. For details of other uses of these interesting lamps reference may be made to a communication in NATURE, March 16, p. 343.

The Speckled Wave Front of Light.

IN view of Sir J. J. Thomson's suggestion (quoted by Reiche, "Quantentheorie," p. 25) that the wave front of light may have a speckled structure, it may be asked whether anything peculiar happens when two specks, belonging to different waves, collide. They might, for example, be deviated from their courses. If so, one light wave would cause some scattering of another wave with which it collided, and the direct light in the second wave would be dimmed. This effect, if it exists at all, must be small or it would have been noticed. Evidence as to its existence might be obtained in the following way. The supposed dimming of the second ray would be likely to depend on the angle between it and the first ray. On this supposition the brightness of a star lying on the ecliptic would vary slightly with the angle between it and the sun, as seen from the earth. Russell (*Astrophys. Journ.*, vol. xliii., 1916) has shown that the brightness of the moon does so vary, but that has been explained otherwise.

On the Maxwellian view of light the reduction of observations which is here suggested appears so meaningless that it has possibly never been tried.

The Royal Academy of Belgium.

By Professor CHARLES SAROLEA, LL.D., Foreign Member of the Royal Belgian Academy.

IN connection with the celebration this week of the one hundred and fiftieth anniversary of the Royal Academy of Belgium a volume has been prepared recording the varied activities of the Academy since its foundation in 1772.[1] Each section of the volume has been allotted to a specialist. M. Paul Pelseneer, the Permanent Secretary, contributes a luminous general introduction and a history of the Prize Foundations of the Institution. M. Stroobant contributes the mathematical and physical section; Prof. Massart writes on the biological sciences and M. Fourmarier on the mineral sciences. The historical sciences have been undertaken by Prof. Pirenne, the philological sciences by Prof. Thomas, the juridical sciences by M. Cornil, the philosophical sciences by Prof. Leclère, the economic sciences by Prof. Mahaim. M. Lucien Solvay and M. Paul Bergmans deal with painting, sculpture, engraving, and architecture.

The celebration of the one hundred and fiftieth anniversary of the Academy is deservedly an event of national import. The Royal Academy of Belgium has been closely identified with the intellectual and artistic life of the Belgian people, much more closely perhaps than any similar body on the Continent, because in Belgium the Academy has been the only important public institution discharging the function of intellectual leadership.

The commemoration will be all the more enthusiastically celebrated because during the war the Royal Academy, although its corporate life was interrupted for four years, incarnated the patriotic conscience of the Belgian people. During the war the German invaders took possession of the imposing palace which the Academy has occupied since 1874, polluted its premises, stole its books and archives, and imprisoned or deported several of its most illustrious members. The reply of the Belgian Academicians was to raise again and again indignant and courageous protests against the brutal policy of the enemy; and their fitting revenge was the recent publication by the Academy of a collection of photographs illustrating the shocking acts of vandalism perpetrated by the apostles of German Kultur.

When the Belgian Academy was founded in 1772 under the reign of Maria Theresa, literary and scientific life was virtually extinct in the Belgian provinces. Historians have often emphasised the contrast between the intensity of artistic life in Belgium and the sterility of literature and science. In the sixteenth century, Belgium still produced men of science of world-wide fame such as Mercator, Ortelius, Simon Stevin, von Helmont, Vesalius, just as Belgian literature in the fourteenth and fifteenth centuries produced a Froissart and a Commines. But from the end of the sixteenth century for two hundred years Belgian literature and Belgian science are almost barren, at the very time when Belgian painting enters its golden age. The explanation of this contrast between the prosperity of art and the paralysis of literature and science is obvious. Art may flourish under conditions of political servitude. On the contrary literature and science demand political freedom. Unfortunately from the end of the sixteenth century the Belgian provinces, unlike the Dutch, were reduced to a state of political slavery.

The foundation of the Belgian Academy in 1772 coincides with the political awakening of the Belgian people. After two centuries the Belgians prepare to shake off the foreign yoke. They are only linked with Austria by a loose political connexion. Unfortunately the Academy is scarcely launched when the French Revolution and the Civil War which follows suspend its activities. Nor can the new Institution be restored under Napoleon. The Emperor had had too many unpleasant relations with the French Academy and with the ideologists of the French Institute to feel disposed to encourage abroad independent scientific or literary institutions. Moreover, apart from his suspicion of Academies in general, he looked upon Belgium as a conquered province and as a mere department of the French Empire.

The Academy was restored in 1816 after Waterloo, by the Dutch Government; and it is interesting to note to-day, at a time when the conflict about the use of the Flemish and the French languages has become acute in Belgium, that even under Dutch supremacy French did remain the sole official language of the Academy of Brussels. But it was not merely the French language which retained its supremacy; the very organisation of the Academy tended to follow French models rather than German or English. When the constitution of the Academy was finally adjusted in 1845, its organisation came to resemble very closely that of the French Institute. It contained the three classes, physical and mathematical science, fine art, and letters. This third class was itself eventually subdivided into the two sections, the historical and philological sciences, and the moral and political sciences. The three classes and four sections of the Belgian Academy therefore answer exactly four of the sections of the French Institute. The chief difference between the two institutions is that there is nothing in the Belgian Academy corresponding to the fifth and most famous section of the French Institute, namely the French Academy. The French Academy mainly represents pure literature, whereas literature pure and simple is excluded from the Belgian Academy. To do justice to the claims of literature, the Flemish Men of Letters constituted themselves in 1888 into a separate Flemish Academy. In 1921, the Franco-Belgian writers followed their colleagues by establishing an Academy of French Literature.

There is one essential feature in which the Belgian Academy resembles the French Institute rather than the Royal Societies of London and Edinburgh; we refer to the strict limitation of its membership. A sure instinct convinced the founders and organisers of the Academy that its influence must needs be in inverse ratio to its numbers. The membership of each class has therefore been restricted to thirty Belgian members with an equal number of foreign associates. It is probable that if the numbers of the Belgian Royal Academy had been increased to some seven or eight hundred as in the case of the Royal Society of Edinburgh,

[1] L'Académie Royale de Belgique depuis sa fondation (1772–1922). Pp. 343. (Bruxelles: M. Lamertin; M. Hayez, 1922).

its authority and prestige would have been very different. It is a high honour to be selected one of a small élite. It is a doubtful compliment to be included in a miscellaneous crowd, and one may not feel very proud to add the letters F.R.S.E. after one's name.

It is not too much to say that the history of the Royal Academy of Brussels for the last hundred years is the history of Belgian science and Belgian learning. Nothing is more remarkable in its activities than the universality of their range. The Academy may claim among its members men of world-wide reputation in every branch of activity. It has produced mathematicians and physicists like Quetelet and Stas; naturalists and chemists like van Beneden and Spring; jurists like Willems and Thonissen; historians like Gachard, Kurth, Cumont, and Pirenne. Looking at the record of those eminent men, Belgium is entitled to a high place amongst the smaller powers of Europe. In one important respect the Royal Academy of Belgium has set an example even to larger and more ancient institutions. It has encouraged research and learning not only by the number and value of its publications. The publications of the Academy constitute indeed a considerable library and are perhaps only rivalled by the editions of that illustrious national seat of learning, the Academy of Cracow. It has published over two hundred volumes of Memoirs, one hundred volumes of bulletins, a collection of about one hundred volumes of the national writers of Belgium, including the Chronicles of Froissart and Commines and Jehan le Bel. In addition it has published a Dictionary of National Biography of which twenty-two volumes have already appeared, and last but not least, it has issued one hundred and thirty volumes of Belgian Chronicles.

The literary activity of the Academy has been all the more useful because Belgian writers, owing to the exiguity of the national territory, can appeal only to a small audience and are generally depending on the support of the French reading public. That activity has been all the more creditable because hitherto the Belgian Academy has had no legal status and for that reason it cannot administer directly any funds or property which may be left to it.

There are good reasons to hope that in the near future the Belgian Academy will at last be endowed with its civil and legal personality. Under that new regime, under the patronage of an enlightened sovereign, and with a national conscience which has been quickened by the tragedy of the war, the Royal Belgian Academy may look forward to an enlarged sphere of scientific and literary usefulness. The present historical record of the institution may therefore be accepted not only as a fitting tribute to the past, but as the promise of an even more brilliant future.

The Cause and Character of Earthquakes.[1]

By R. D. OLDHAM, F.R.S.

THE stress-difference required to produce fracture in average hard rocks, as they are met with at the surface, is round about 1,000,000 grammes per centimetre square, and, allowing for the greater strength at depth, which is indicated by the experiments of Prof. Adams and the computations of Prof. Barrell, we may put the breaking strength of the earth's crust at about double this quantity, so that to reach this point in one year from starting, the strain would have to increase at the rate of about 1400 grammes per centimetre square in each quarter of a day. According to the late Sir George Darwin the stress-differences set up by the moon in the latitude of Italy would amount to about 20 grammes per centimetre square in an incompressible Earth, and in a compressible Earth with an incompressible crust, a condition much more akin to what we have reason to suppose is the reality, the stress-differences would be many times this figure; but even the lower amount is nearly $1\frac{1}{2}$ per cent. of the growth required to reach breaking point in one year; it would be close on 15 per cent. if the period is increased to ten years, and, with anything approaching this proportion, a periodicity would result which could not have escaped detection before now.

The figures, therefore, give us a lower limit of the rate of growth of strain; it must have been something faster than that needed to reach the breaking point in one year from starting, if the differences on which the argument is based are real. But are they real? The actual amount of difference, barely one per cent. of the mean, is so small that it may well be fortuitous, and the true interpretation may be that the gravitational stresses, and the stress-differences produced by them, have no effect whatever in determining the time of occurrence of an earthquake. If this be so, then the rate of growth of strain becomes infinite, and each earthquake becomes the result of a development of strain, akin to an explosion in its suddenness.

The truth may lie anywhere and must lie somewhere between these extremes, so we reach the conclusion that there is no support for the commonly accepted notion of a continuous, slow growth of strain, extending over years, decades, or even centuries, before the breaking point is reached; on the contrary, it appears that the cause of earthquakes must be a rapid growth of strain. This strain cannot be developed without some deformation, but the magnitude of this has no relation to the frequency or magnitude of the earthquakes; if change of form is slow and prolonged, relief may be provided by gradual yielding, if rapid, a very small amount of distortion may lead to fracture, and on the extent, form, and position of this fracture will depend the character of the resulting earthquake.

This study of the rate of growth leads to the question, which is the really important one in its bearing on geology, of how the strain is produced. It can scarcely be the result of those tectonic processes which result in folding, for these must necessarily be slow in their action; the change of form involved in the bending of solid rock from its original shape into complicated folds, without breach of continuity, can only have been a slow one, and, as we have seen, the deformation which produces earthquakes must be a rapid one. With faults the case is different; many

[1] Continued from p. 653.

earthquakes are known to have been accompanied by movement along pre-existing fault-places, in others the origin evidently agrees in position with known faults, and in all of these the distribution of the intensity of disturbance is closely correlated with the faults, being greatest in proximity to them and decreasing as the distance becomes greater. So much is indisputable, yet in spite of a general acceptance of the explanation that the earthquake was a result of the same process which gave rise to the formation of the fault, it must be recognised that the proof is not logically complete, for it might be that the cause and process, which gave rise to the earthquake, were wholly different from, and independent of, those which produced the fault, the only connection being that the weakness, resulting from the fault fracture, served to localise the yielding and so controlled the distribution and intensity of the earthquake. In a study of the Californian earthquake of 1906, where the greatest intensity of disturbance ranged along the line of the San Andreas fault, and was accompanied by considerable displacement and distortion of the surface along the fault-line, I was able to show that the earthquake was due to some cause quite distinct from that which produced the fault, and that neither was the fault the cause of the earthquake, nor the earthquake an incident in the formation of the fault.

Much more weighty and suggestive evidence is to be derived from some other great earthquakes which have been studied in detail. The conclusion drawn from the Californian earthquake is more fully exemplified by the Indian earthquake of 1897. Here there was no single leading fault and zone of maximum intensity of shock, but a complicated network of lines of extreme destructiveness ramifying over an area not much different in area from that of England, and extending right across a series of great tectonic features, across the great monocline of the southern face of the Assam range, across that range itself, across the alluvial plain of the Brahmaputra Valley, the great boundary faults of the Himalayas, and probably even across the main axis of elevation of the range.

A still more instructive instance is the Charleston earthquake of 1886. There, in a region as devoid of any great structural feature, either of folding or faults, and as little subject to earthquakes, as could be found in our own country, there suddenly occurred a great earthquake, of destructive violence in the central area, and felt over an area measuring about 1500 miles across. It was an earthquake of first-class magnitude, whether we regard the maximum violence of shock, or the extent of area affected, yet there is nothing in the structure of the surface rocks which would suggest its origin being in any tectonic process, and equally nothing which could lead to its classification as volcanic. If we accept the conclusions of Col. Harböe, regarding the character and extent of earthquake origins, the absence of any connexion between the origin of the earthquake and the tectonics of the surface rocks becomes absolute, for, according to this interpretation, the origin becomes almost coextensive with the seismic area, and the diminution of violence in the outer portions is not due solely to enfeeblement, resulting from the elastic propagation of the earthquake wave, but very largely to a diminution in magnitude of the originating impulses.

The interpretation is, I believe, in the main, well founded, and, if it be true that earthquakes of great extent are due to systems of fracture, or analogous disturbance, ramifying over, and practically coextensive with, the seismic areas, of which the dimensions in any direction may be measured in hundreds of miles, it becomes more than ever necessary to recognise that earthquake origins cannot be the result of processes and displacements recorded, and indicated by, the tectonics of the surface rocks. The real and ultimate origin must be more deep-seated, and involve either a displacement of, or a change of volume in, the material underlying the outer crust.

This is no occasion to enter into detail, so I have merely indicated the general character of the studies which have gradually forced me to the conclusion that great earthquakes, and also to a large extent those lesser ones which are commonly classed as tectonic, do not owe their origin to the tectonics of the outer crust, but to processes and changes which take place in the material below it. What these processes may be we cannot know with the certainty which comes from direct observation, for such knowledge as we think we have comes from inference, deduction, and, to some extent, simple assumption, but suggestions have been made which possess a considerable degree of probability. Among these, and especially apposite to present considerations, may be placed Dr. L. L. Fermor's studies of the changes in mineral aggregation which may take place in the solidification of a magma; he has suggested that the determining factor in deciding the form in which the rock finally solidifies is the interrelation of pressure and temperature, and has shown that the change of volume, consequent on the change from one mode to another, may amount to more than 20 per cent. in extreme cases. Mr. W. H. Goodchild has also studied the subject from another point of view, and suggested that some of the changes, especially the separation of metallic sulphides, take place with great, even explosive, rapidity.

It is not improbable that, in the material beneath the outer crust, changes of this character are taking place, some slow and gradual, others more rapid and sudden, but all accompanied by a greater or less change of bulk, either of increase or decrease; and if this be accepted we find an explanation, not only of the forms and origin of earthquakes, but of many other phenomena which are difficult of explanation on any hypothesis of contraction and compression alone. On one hand, slow movements of elevation such as that of the northern Scandinavian region may be attributed to slow and gradual change, involving the whole bulk of large masses; the lesser earthquakes may be due to more rapid changes in smaller portions; the greater to transformation involving a larger bulk of material, and possibly a more abrupt change of combination and density; while the greatest earthquakes, of first-class magnitude, result from similar changes involving still a larger bulk of material and greater change of bulk.

To elaborate these considerations forms no part of my purpose; enough has been said to show that, even

in our very fragmentary knowledge of what goes on within the substance of the earth, we have means of explaining and interpreting the greater part of the facts known to us regarding the character of earthquakes. I shall, therefore, conclude by summing up the conclusions which have been put forward as to origin and cause. These are, first, that earthquakes are not due to any slow-acting process of secular duration, but to a rapid development of strain, which may, in extreme cases, be almost instantaneous—a conclusion which I believe to be true of the greater part at least of those usually classed as tectonic, and of all those of great magnitude; and, secondly, that the development of strain is not the result of processes which have produced the tectonic structures, recognised by surface observation, but of changes and displacements in the matter which lies below the cooled and solid outer crust.

Telegraphic Transmission of Photographs.

A NUMBER of experimenters have attained varying measures of success in solving the problem of transmitting photographs, drawings, handwriting, etc., by line and wireless telegraphy, and a good deal of attention has been directed recently to the latest developments of the system on which M. E. Belin has been working in France for some time. His apparatus has been used with good results between the large French wireless station near Bordeaux and a naval station in the United States, as well as over land telephone circuits, etc. A brief description of the latest form of the apparatus appeared in the *Comptes rendus* of the Paris Academy of Sciences of March 6, from which the accompanying illustration is reproduced (Fig. 1).

FIG. 1.—Portable apparatus for the telegraphic transmission of photographs.

As in most of the experimental systems of "telephotography," synchronously rotating drums are made use of in the sending and the receiving apparatus respectively, with a simple arrangement of correcting signals to keep them in step. Mounted on the cylinder of the sending apparatus is a print of the photograph to be transmitted, made on a special bichromatised film which gives an image in appreciable relief. It is not necessary, however, to metalise this image to render it conducting, as is necessary in some systems, and it will be seen that the use of selenium cells, which forms a feature in other systems, is also avoided. A stylus, in a holder which is given a slow axial feed, is caused to pass over all portions of the relief film in succession, after the manner of the needle of a phonograph. This stylus is attached to the diaphragm of a simple but sensitive form of carbon granule microphone, included in a suitable circuit, arranged so that a current of varying strength is produced, owing to the variations of the resistance of the microphone according to the thickness of the part of the film that is being passed over. This varying current can either be sent directly over the line, or can be employed to control the strength of the waves sent out, in the case of wireless transmission.

The manner in which the variations in the signal current, or wave train, are retranslated into a photograph by the receiving apparatus is scarcely more complicated. The varying current from the line (or the wireless receiving apparatus) is passed through a delicate reflecting galvanometer such as a Blondel oscillograph, the mirror of which is deflected by an amount depending on the strength of the current, *i.e.* on the thickness of the film where it is being passed over by the stylus of the transmitting apparatus. The light from the mirror passes through a screen of graduated capacity, and the optical system is arranged so that an image of the mirror, varying in brightness according to the deflection, is projected on to a photographic film on the drum, which is moving synchronously with that in the transmitting instrument. The photographic effect produced at any point is therefore always proportional to the thickness of the original film, so that a duplicate photograph formed of a screen of fine lines, but with a full range of "half-tones," is produced. In a simpler form of the apparatus, for pure black and white or "line" work only, a contact-maker replaces the variable resistance microphone in the transmitting apparatus, and a diaphragm, which

cuts off the light altogether when the mirror is deflected, is used in place of the graduated screen in the receiving apparatus.

M. Belin has perfected a portable form of the transmitting apparatus for connection to any telephone line. Considerable possibilities, both in illustrated journalism and in police work, by the prompt transmission of portraits, finger-prints, handwriting, etc., are opened up by apparatus of this kind, and obviously the system preserves secrecy, as regards all ordinary listening-in apparatus, as the actual signals sent furnish no clue to the nature of the picture being transmitted.

Current Topics and Events.

On May 17 the House of Lords, again prompted by Lord Sudeley, asked the Government to encourage the educational use of museums, and the Government, by the mouth of Lord Hylton, expressed the willingness of the Treasury "to consider in a very sympathetic spirit any further requests" for the appointment of guide-lecturers, also its own "desire to encourage all steps that can be taken to develop the sale of" photographs and other reproductions of objects in the national museums. Fair words! And progress has been made since the debate initiated by Lord Sudeley fourteen months ago. How does the Government translate word into act? It has just cut down the grant for the production of these popular publications, and, if its threat to reimpose admission by payment be enforced, it will deal a severe blow at the whole business and at the usefulness of the guide-lecturers. Never was anything so ridiculous perpetrated in the name of economy. That the sale of publications is a source of income is admitted by the Treasury. At the British Museum (Bloomsbury) an advanced policy has raised the receipts under this head from 3400*l.* in 1920–1921 to 6200*l.* in 1921–1922, thus more than paying for the whole cost of guide-lecturers. The introduction of pay-days will inevitably check this sale, and what will it bring in? The average receipts from admission at the Victoria and Albert Museum during the twelve years the system was in force were about 650*l.* per annum. At the Natural History Museum an expensive stall has just been fitted and saleswomen engaged, and now the authorities expect to have to spend 250*l.* on turnstiles and to lose 400*l.* on sales. One after the other the leaders of industry tell us that the secret of recuperation is more production; yet the Government, when it has a paying business, proposes to economise by checking production.

The Metropolitan-Vickers Electrical Co., Ltd., which has a large works at Trafford Park, Manchester, devoted to the manufacture of electrical machines and apparatus, proposes to take up the manufacture of radio receiving equipment, and for this purpose will work in conjunction with the Radio Communication Co. of London. The Radio Communication Co., which is associated with the Indo-European and Eastern Telegraph Cos., was formed in 1919 to carry on business in connection with the establishment of radio telegraph and telephone installations and is well known for its important work during the war. The manager of the Metropolitan-Vickers Co.'s Research and Education Departments, Mr. A. P. M. Fleming, has been negotiating during the last few months with the Postmaster-General with reference to the establishment of broad-casting stations, and the companies propose to establish two stations immediately, one at Trafford Park, Manchester, and the other at Slough. Other stations are projected as required. Immediately the official arrangements are made with regard to the areas to be covered and sites of the broad-casting stations, active steps will be taken to provide suitable programmes for broad-casting and to manufacture the necessary receiving equipment. The Westinghouse Co. of America initiated the broad-casting of information and entertainment by radio telephony and has very extensive experience in connection with it. The Metropolitan-Vickers Co. is technically very closely associated with the Westinghouse Co. and will be able to draw upon this unique experience, which with the utilisation of a number of fundamental patents in connection with wireless telephony, the experience of the Radio Communication Co. and its own selling, manufacturing, and research organisation, should place the Company in an exceptionally favourable position in entering this new field.

A telegram has been received from Fiji reporting the successful treatment of more than 12,000 hookworm cases by carbon tetrachloride with 90 per cent. of cures with one dose, and the removal of 98 per cent. of the worms. This method was tried first on dogs by Dr. Maurice C. Hall of the United States Bureau of Animal Industry, who found that 0·3 c.c. of the drug for every kilogram of live weight expelled all the hookworms of those animals, a result he had never previously obtained by any other method of treatment, while it could be given after fasting in hard gelatin capsules without purgation being necessary. As the new drug is much less toxic and far cheaper than either thymol or oil of chenopodium, the last of which has given rise to a number of fatalities owing to the uncertain amount of the active principle in different samples, these are matters of great practical importance, and the remarkable success of the trial now reported will, if confirmed by further observations, prove a notable advance in dealing with this the most widespread health- and labour-destroying scourge of immense areas of the world.

With reference to the reported discovery of a stage of the *Leishmania donovani* parasite of kala-azar in the salivary gland of a bed bug in Assam, information has now been received that Lt.-Col. Christophers, I.M.S., has reported the specimens of Mrs. Aidie to show only a normal parasite of the bed bug, which has no relationship to the organism of kala-azar, so the solution of the problem of the carrier of that disease is still incomplete.

THE revised scheme for poultry research of the Ministry of Agriculture, which was foreshadowed by Sir Arthur Griffith Boscawen at the Poultry Club dinner last October, has been approved by the Development Commissioners. Of the grant of 50,000*l.*, 19,500*l.* will be devoted to capital expenditure and the balance to maintenance during five years. The grant is conditional on the sum of 6500*l.* being provided by the industry, and apparently any further grant will depend on results. So that the seedling will have to be planted, pruned to shape, and brought into profit in five years. The provisional scheme includes: (*a*) An experimental section at the Harper Adams College, capital 15,000*l.*, maintenance grant 2000*l.* a year; (*b*) experiments in egg production, 2500*l.* and 725*l.*; (*c*) experiments in the production of table poultry, 1500*l.* and 725*l.*; (*d*) research at the Cambridge School of Agriculture, 5000*l.* and 300*l.*; (*e*) experiments in nutrition at the same school, 500*l.* and 1000*l.*; (*f*) diseases research at the Ministry's Addlestone Laboratory, 1500*l.* and 1250*l.* Much will depend on the personnel of the "advisory committee." Sections (*b*) and (*c*) will be supervised by representatives of the local poultry societies. It is hoped that the scheme may lead to an improvement in British methods of poultry production; hitherto deplorably unscientific.

THE Forestry Commissioners announce that a prize of five thousand dollars is offered by Mr. Frank J. D. Barnjum of Montreal for a practical method of combating and suppressing the spruce bud worm, bark beetle, and borer, which have caused such tremendous damage in the forests of Eastern Canada and the United States. The Province of Quebec alone has suffered a loss during the past ten years of 150,000,000 cords of standing pulpwood by these pests, which represents a market value in pulpwood of three billion dollars, or if manufactured into paper, of seven billion dollars. This represents a loss of wood sufficient for forty-five years' requirements for newsprint for the North American continent. The competition will close on August 1, and the 5000 dollars will be given for the successful suggestion that is accepted by the judges, who will be Sir William Price of Messrs. Price Bros., Quebec; Dr. C. D. Howe, Dean of the Faculty of Forestry, Toronto University; Mr. Fred A. Gilbert, Great Northern Paper Company, Bangor, Maine; Mr. G. C. Piche, Chief of Forest Service, Quebec, and Mr. Ellwood Wilson, Laurentide Company, Grand Mere, Quebec. Competitive suggestions should reach Mr. Frank J. D. Barnjum, New Birks Building, Montreal, Canada, before August 1.

ONE encouraging sign after the war is the increased interest being shown in the Yorkshire Philosophical Societies, most of which were founded about a century ago. The Whitby Society has just had its most successful year; the Scarborough Philosophical Society is also picking up; the Hull Society is celebrating its centenary this year, and the York Philosophical Society next year. This last has issued a pamphlet and an appeal for 75,000*l.* in order to extend its museum and properly to preserve the wealth of archæological material within its grounds. Fortunately, through the generosity of the late Dr. Tempest Anderson, the society was recently very much relieved of its financial anxiety, and under the regime of the new Keeper, Dr. Collinge, efforts are being made to enlarge the museum and to take the necessary steps towards preserving St. Mary's Abbey and the Hospitium. The pamphlet accompanying the appeal contains illustrations from photographs of St. Mary's Abbey, the galleries devoted to mammalia and birds, and the unique bronze mortar belonging to St. Mary's Abbey which is dated 1308—probably one of the earliest dated pieces of this kind in the country. We notice one of the objects of the appeal is to provide "a *Yorkshire* museum up to the standard of modern requirements." Seeing that most of the important towns and cities in the county now have their museums, the museum at York will probably have more than sufficient for its requirements if attention is confined to the antiquities of the city and its immediate area.

THE thirty-third annual conference of the Museums Association will be held at Leicester on July 10–July 14 next, under the presidency of Mr. E. E. Lowe, Director of the Museum, Art Gallery, and Libraries, Leicester. The subjects for discussion at the conference are to deal more particularly (though not entirely) with the practical and technical side of museum work, and the secretary (Dr. W. M. Tattersall, The Museum, The University, Manchester) will be glad to receive offers of papers of this nature as early as possible. An exhibition of appliances, fittings, apparatus, and cases appertaining to museum work, by commercial firms who supply these things is being arranged with a view of the mutual interchange of ideas between Curators and business men. Visits will be made to the Museum, the Art Gallery, the Library, and the newly founded University College, and it is hoped that arrangements will be possible whereby the members attending the conference will be able to inspect one of the staple manufactories of the town. Excursions to the pre-Cambrian area of Charnwood Forest and to the granite area of Mount Sorrel are contemplated. The duties of hon. local secretary have been undertaken by Mr. W. Keay, 6 Millstone Lane, Leicester.

THE annual report of the Zoological Society of London for 1921, presented at the annual general meeting on April 28, records a net increase of 129 in the number of fellows of the Society, while the number of visitors to the gardens, though nearly 200,000 less than the million and a half of 1921, is still the third largest in the history of the Society. The scheme of lectures to school teachers, arranged in 1910 in co-operation with the London County Council, was continued, and Mr. F. Balfour-Browne conducted two courses of four lectures with lantern demonstrations and three tours of the gardens, each course arranged for 150 teachers. The future of the "Zoological Record" has received the serious consideration of the Council, and the volume for 1921 has been

started in the hope that the support appealed for will be sufficient to justify publication and so save this valuable compilation for zoologists both in this country and abroad. Special mention is made of the valuable collection of water-colour drawings of ornithological subjects bequeathed by the artist, the late Major Jones, a collection of almost unique artistic beauty and ornithological interest. The collections of animals from Nepal and Malaya presented by H.R.H. Prince of Wales, will be exhibited in a special part of the gardens during the summer of 1922. Among the proposed new works for 1922, the most important are the provision of better accommodation for the refreshment department and the suggested aquarium on the Mappin Terraces for fresh-water and marine animals. A proposal to place coloured labels on the cages and enclosures containing different species, as a means of identification for visitors, is one that will commend itself. Experiments with coloured drawings painted on tiles and afterwards fired promise success in the production of a form of label which is weatherproof. There can be no doubt that the provision of such labels will prove of great service to visitors to the gardens.

ON Tuesday next, May 30, Sir Percy Sykes will deliver the first of two lectures at the Royal Institution on (1) "Travel in Persia," (2) "Foundation of the Persian Empire." The Friday evening discourse on June 9 will be delivered by Mr. Joseph Barcroft on "Physiological Effects at High Altitudes in Peru."

THE following have been elected officers and new members of council of the Institution of Electrical Engineers for 1922–1923: *President*, Mr. F. Gill; *Vice-Presidents*, Dr. W. H. Eccles, and Mr. A. A. Campbell Swinton; *Honorary Treasurer*, Sir James Devonshire; *Ordinary Members of Council*, Mr. J. W. Beauchamp, Mr. R. A. Chattock, Mr. F. W. Crawter, Mr. D. N. Dunlop, Major K. Edgcumbe, Mr. A. F. Harmer, and Mr. W. R. Rawlings.

AT the annual general meeting of the Chemical Section of the Manchester Literary and Philosophical Society held on May 5, the following officers and members of committee were elected: *Chairman*, Mr. Leonard E. Vlies; *Vice-Chairman*, Dr. H. F. Coward; *Hon. Secretary*, Mr. David M. Paul; *Committee*, Dr. David Bain, Dr. W. H. Bentley, Mr. David Cardwell, Mr. R. H. Clayton, Dr. J. A. R. Henderson, Mr. Harold Moore, Miss Rona Robinson, Prof. F. C. Thompson, and Dr. J. C. Withers.

WE have received from the Eastman Kodak Company, Rochester, New York, their latest price list of Eastman Organic Chemicals. Several new chemicals have been added. The list is noteworthy in that it now includes melting- and boiling-point data for the majority of the chemicals determined from actual laboratory observations. This feature should make it useful to chemists.

Our Astronomical Column.

NEW COMET.—A faint comet, 1922 *b*, was discovered by Mr. Skjellerup at the Cape on May $17^{d.}\ 6^{h.}$ G.M.T., in R.A. $7^{h.}\ 53^{m.}\ 44^{s.}$, N. decl. 19° 32′. Daily motion $+6^{m.}\ 40^{s.}$, N. 1° 28′. The comet is an evening object, and its motion is bringing it into a more favourable position for observation.

CHANGES ON THE MOON.—In a paper by Prof. W. H. Pickering in *Popular Astronomy* for May two drawings are reproduced of the lunar crater Eratosthenes by Dr. Maggini. Prof. Pickering shows that these corroborate strongly his own work, and establish fully the reality of the changes of aspect. He notes that the markings cannot be shadows, since they are visible at full moon, and one of them approaches the setting sun, instead of receding from it; but he has not, perhaps, considered sufficiently the possibilities arising from the different changes of reflective power, according to the angle of incidence, that are shown by different substances. It is generally agreed that at least two lunar phenomena—the increasing visibility of the bright rays as the sun's altitude increases, and the darkening of the floor of the crater Plato under the same conditions—arise in this way. Prof. Pickering estimates the density of the lunar atmosphere as $\frac{1}{150}$ of that on earth, and supposes that enough water vapour and carbon dioxide might be emitted from the craters to support low forms of vegetation.

PROF. BROWN'S NEW LUNAR TABLES.—Prof. Brown in his tables, which are used for the first time in the Nautical Almanac for 1923, deliberately adopted the secular acceleration arising from the change in the eccentricity of the earth's orbit, regarding the larger value deduced from ancient eclipses (generally ascribed to the tidal retardation of the earth's rotation) as too uncertain to use. Many will consider that in this respect he showed some lack of judgment, for Dr. Cowell's discussion of the old eclipses was available before the tables were put into final form. However, he now admits his conversion to the larger acceleration, which has been effected by Dr. Fotheringham's papers on the old eclipses and occultations, and the researches of C. I. Taylor and Dr. H. Jeffreys (misspelt Jeffries by Prof. Brown) on tidal friction in the Irish Sea and similar semi-landlocked waters. In a paper in the *Astronomical Journal*, No. 799, he gives the results of an increase of the moon's secular acceleration from 7·12″ to 11·91″, with the resulting changes in some other constants. He notes that the change makes little difference in his tabular places up to the year 1890, but that it makes a decided improvement since that date, which is another argument, though not a very strong one, for the larger acceleration. Brown's tables thus modified represent the moon's longitude correctly for the end of 1905; after that the moon went ahead of the tables, reaching a maximum of nearly 5″ in 1918; it now shows signs of diminishing again. A small table enables the new correction to be applied to Brown's longitudes of the moon up to the year 1940, when its value is 7·44″. This table will be of use in predicting eclipses, or for other purposes where an accurate prediction is desirable. The paper also gives a list of the errata detected in the new tables; these are chiefly in the explanatory matter, but one refers to the tables themselves.

Research Items.

SEX DEVELOPMENT.—Miss R. M. Fleming, of Aberystwyth University, publishes in the May issue of *Man* the results of her measurements of a large number of women and children, which throw valuable light on the problems of sex development. The results, so far as they admit of tabulation, indicate a decided difference in the rate of development between boys and girls, which may prove of use in their grouping and grading for educational purposes. Until the age of 8 years, girls showed rapid increase in cephalic index and marked changes in colour, while from 9 years onward, the changes were much slower and less marked. Boys showed only slight alterations in colour or in increase of cephalic index until the age of 10, but from 10 years onwards changes were rapid and marked. In the change in the shape of the forehead, boys and girls differ more than in any other feature. The continuous frontal boss of infancy seems to disappear in girls a year or two earlier than in boys, resolving itself in the case of the latter often into two bosses, which mark the nuclei of growth in the frontal bone and interrupt the general tendency of the forehead to recede. It is hoped that the study of these data may help by making it possible to suggest to boys and girls who are undecided about their future careers, lines of thought which will prevent wasting time in trial of a wrong scheme of life.

LIFE TABLES.—Dr. Major Greenwood dealt with the scientific value of life tables at a recent meeting of the Royal Statistical Society. He submitted that the value of a life table as an instrument of research has been over-estimated; a life table is an artificial product and its population is a fiction. It is not correct, for instance, to say that the average length of life of an English male is given by the "expectation of life" of any national table. An "expectation of life" is deduced from the rates of mortality of contemporaneously observed lives and the comparison of such constants for different life tables is open to criticism. Dr. Greenwood is of opinion that a Medical Officer of Health can learn little more from a life table than from death rates at ages.

THE DIALECT OF SOMERSETSHIRE.—The Somerset Folk Press has started a movement for preserving the local dialect by the publication of a series of handbooks, the first of which is entitled "Selected Poems in Somerset Dialect." It contains a number of poems and ballads by James Jennings, born in 1772; George Parker, who died in 1888, aged 92; and other local writers. In an interesting foreword the editor, Mr. Walter Raymond, points out the value of the county as a field for research. Within its million acres it contains a richer variety of natural features than almost any part of England. The variety of its natural structure is the reason for the abundance of its flora and bird life. There is a wealth of local legend, both early Christian and Arthurian. "Many races—since forgotten tribes raised tumuli on the crests of our hills—have made their contributions to our lore. Briton, Scandinavian and Saxon all left their mark on the beliefs and superstitions which still linger amongst our folk. Even the lake-dwellers at Glastonbury may have cast their mite into our treasury of folk-lore." Roman roads and masonry, feudal castles, and ancient Christian remains carry on the story. It would be well if other counties followed the excellent example of Somerset in preserving folk-lore and dialect.

EARTH SMOKING-PIPES.—Convicts in Indian prisons and coolies marching with their loads through passes in the hills, in the absence of the common hukka or water-pipe, indulge their craving for tobacco by making a small tunnel in the earth; a little tobacco is set alight at one orifice, and the smoker, kneeling on the ground, sucks up the smoke from the other end. Mr. Henry Balfour, in the May issue of *Man*, publishes examples of various types of earth-pipes from South Africa and Asia. In South Africa the pipe is either built up on the ground-surface or excavated below it. In Baltistan the tunnel is constructed by thrusting in and then withdrawing a stick from the earth which has previously been patted down. A further extension of the method is illustrated from Natal and Rajputana, where the pipe is a tapering tube of baked clay, sun-dried mud, or camel dung; the wider end serves as "bowl," the narrower as mouthpiece, and there is no demarcation between the two, the bore tapering gradually from one end to the other. Mr. Balfour inclines to suppose that the similarity of practice between Africa and Asia represents a culture-link between the two widely separated areas; but it seems not impossible that similar needs may have suggested this simple method of supplying them. The publication of this paper may lead to the discovery of further examples which may settle the origin of this curious practice.

THE EXTERNAL WORLD.—Physicists and philosophers interested in the problem of the hypothesis of the external world as it is discussed in the works of Helmholtz, Mach, and Einstein may be glad to have their attention directed to two articles by Karl Gerhards of Aachen in the Berlin scientific weekly *Die Naturwissenschaften* for April 28 and May 5, entitled "Der mathematische Kern der Auszenweltshypothese." It is impossible to explain the author's scheme without his diagrams, but it is certainly ingenious, however unconvinced it may leave us in regard to its theoretical or practical value. He attempts to relate the two parallel series, the flow of sensible appearances and the flow of physical reality, by constructing a mathematical model on the analogy of the kinematograph camera. For the observer behind the camera there is a series of "phanograms"; these correspond, of course, to Mach's series of sensations. The author then correlates these by a mathematical device with the reality presumed to lie beyond the kinematographic panorama in a three-dimensional world and obtains a series of "ontograms." What he claims is that by his purely mathematical scheme, or as he terms it by this mathematical kernel of reality, he has got rid of the arbitrariness of the parallelist hypothesis, and shown the actual relation between appearance and reality.

THE STEEL INDUSTRY OF SOUTH YORKSHIRE.—In an article in the *Sociological Review* for April, Prof. C. H. Desch traces the geographical and other factors which have led to the origin and growth of the steel industry in and around Sheffield. The article is of value because these factors are often misstated and their persistence is assumed. The use of local iron ore was encouraged in early times by the abundance of timber for charcoal in the forested valleys, and by the hill-top sites where open furnaces could catch the prevailing winds. These conditions were not confined to this particular part of England, but later, when artificial replaced natural draught, the abundant water power of the five streams converging on Sheffield gave unique advantages for bellows driven by water-wheels. The hammer ponds and the ruins of the

forges can be seen in most of the valleys to-day. When the manufacture of cutlery was established higher grade iron ore had to be imported. This occupation demands a high degree of skill, and it became a domestic manufacture. Many survivals of those economic conditions still exist and give a peculiar character to the organisation of labour in Sheffield to-day. Steam power eventually replaced water power, and the industry as a result has crowded on the lower ground. Coke replaced charcoal as metallurgical fuel. Local coal, firestone, and ganister all helped to retain the industry in Sheffield, but as potent a factor as any other is the traditional skill of the workers. This factor still holds the industry to the district, although few of the former advantages of its localisation are now of value.

TERTIARY MOLLUSCA OF SANTO DOMINGO.—A "Revision of W. M. Gabb's Tertiary Mollusca of Santo Domingo," long wanted by students of tropical American palæontology, has now been published in the Proceedings of the Academy of Natural Sciences of Philadelphia (1921, Pt. II., pp. 305-435, pls. xvi.-xlvii., and text figs.). It is the work of the well-known conchologist Dr. H. A. Pilsbry, to whom great praise and thanks are due. Gabb's investigations were conducted in the years 1869–71 and his observations and descriptions published by the American Philosophical Society (Trans. xv.) in 1873. His fossils were presented to the Academy of Natural Sciences of Philadelphia, but unfortunately were not figured, while the descriptions were not always sufficiently full to ensure recognition. Prior to Gabb, Mr. T. S. Heneken had brought fossils from the island to London, and these were described by Moore, G. B. Sowerby, and later by Mr. R. J. L. Guppy. The present work was begun in co-operation with Mr. C. W. Johnson and submitted for publication in 1917; printing had, however, to be deferred and only an extract containing descriptions of the new species appeared at the time. The full work is now presented with some modifications entailed by the work of Miss Maury. The nomenclature has intentionally been left uniform with the 1917 paper, but surely even at that date the use of Pteropoda as a class apart from the Gastropoda was antiquated. A few further new species are included, but the value of the work lies in the more careful diagnoses of the species and the excellent figures, over 480 in number, which do infinite credit to the artist, Helen Winchester.

AUSTRALASIAN NATURAL HISTORY.—The Papers and Proceedings of the Royal Society of Tasmania for the year 1921, recently received, include some articles of great interest and importance. H. H. Scott and C. E. Lord, writing on "Nototheria and Allied Animals," are convinced that several groups of more or less generalised animals lived in the Australian zoogeographical province and "that the names Diprotodon, Nototherium, Phascolonus, Euryzygoma, etc., stand as outpost flags of a largely unexplored realm," and "that the most generalised groups have yet to be reconstructed." Dr. R. W. Shufeldt describes "Skeletons of the Monotremes in the Collections of the Army Medical Museum at Washington [U.S.A.]." Two skeletons of Ornithorhynchus and one of Echidna are described at some length and figured, on the ground that these animals are now becoming rare. W. L. Crowther and C. Lord give a "Description of Two Tasmanian Aboriginal Crania," which will intrigue anthropologists. Prehistorians of the school to which Mr. Reid Moir belongs will find much support from the figures and descriptions of "The Concave Stone Implements of the Tasmanian Aborigines," described by Dr. G. Horne. The Tasmanian specimens are compared with similar ones from south-east Victoria and their mode of use illustrated by reference to the methods of the aborigines of the latter district. Judging from the figures these implements are of the crudest character even when allowance is made for the nature of the material from which they have been chipped. "A Preliminary Sketch of the Glacial Remains preserved in the National Park of Tasmania," by A. N. Lewis, with "Some Geographical Notes on a Model of the National Park at Mt. Field, Tasmania," from the pen of Prof. G. Taylor, furnish together an interesting account of the physical geography of a district which, although small, abounds in features of remarkable character, especially the parallelism of the valleys and the arrangement of some of the lakes therein.

SOME AUSTRALIAN DIPTERA.—G. H. Hardy contributes to the Papers and Proceedings of the Royal Society of Tasmania for the year 1921 a monograph on "Australian Bombyliidæ and Cyrtidæ (Diptera)." This catalogue contains a key to the genera, and descriptions of two new species belonging to genera in which no previous species have been described from Australia. Also there are numerous synonyms suggested, and a number of species have been placed in the genera they more readily conform to than those in which they were originally placed.

METEOROLOGY AT FALMOUTH.—Falmouth Observatory has published meteorological notes and tables for the year 1921. The work is carried on under the auspices of the Royal Cornwall Polytechnic Society by Mr. J. B. Phillips. Observations are supplied to the Meteorological Office, and the Observatory is assisted financially by the Government. The mean pressure for the year was 30·126 in., which is 0·15 in. above the average and a record for the past 50 years. Bright sunshine was registered on 315 days, which is 11 days more than the average, and the total duration was 1817 hours—64 hours above the average. Every month had an excess of temperature, the mean for the year being 53°·6 F., which is 2°·9 above the normal for 50 years. Rain was measured on 186 days, a total 22 short of the average, and the total measurement was 28·9 in., which is 16·7 in. less than the normal for 50 years. The highest hourly wind velocity was 55 miles in a south-westerly gale on March 28, and the strongest gust was at the rate of 77 miles an hour.

AN EFFICIENT SOUND PRODUCER.—In our issue of April 12, 1917, p. 132, attention was directed to the work of Prof. King of McGill University on the efficiency of the compressed air syren used at Father Point, Quebec, for signalling during fog. Of the 100-horse power used only 2·4 was converted into sound. From a paper by Prof. Kerr Grant, of the University of Adelaide, published in the April number of the Proceedings of the Physical Society of London, there appears to be some possibility of producing sound more efficiently. The new apparatus makes use of the vibrations set up in a thin metal plate a foot in diameter. A stream of air or liquid issuing from a flanged pipe, the flange of which is placed near and parallel to the plate, impinges on the latter. The arrangement is a reproduction on a mechanical scale of the scientific toy illustrating Bernouilli's law of flow of fluids, in which a sheet of paper is placed on the end of a flanged pipe and attempts are made to displace the paper by blowing up the tube. In the sound producer, the surface of the flange is made convex to the plate, and the edge of the latter is provided with a strong rim to which the pipe and flange are attached in a way to provide for adjustment of the distance separating flange and plate.

The Royal Society Conversazione.

THE first of the two annual conversaziones of the Royal Society was held at Burlington House on May 17, when Sir Charles Sherrington and the officers of the Society received the fellows and guests. A few of the exhibits were shown last year, and it is an invidious task to select some of the remainder for mention. We have therefore grouped the exhibits on related subjects and propose to describe briefly a few of the items in each group.

Sir Almroth Wright demonstrated methods of measuring the bactericidal potency of the blood fluids and leucocytes. With regard to the microbes that give rise to "blood poisoning" and septicæmia, the capacity for growing in the blood fluids depends on capacity for overcoming the normal anti-tryptic power of the blood and digesting its albuminous substances. Increased destruction of microbes can be obtained by the vaccination of the blood *in vitro*. This is important, for where the patient is unable to respond to a vaccine he can be transfused with a normal blood which has by vaccination *in vitro* been furnished with the protective substances required. The lysozymic action of tissues and secretions was demonstrated by Dr. Alexander Fleming. This inhibitory effect on bacteria is so strong that with tears diluted 1 in 100 it is complete in a few seconds, and it is shown even with tears diluted 1 in 5,000,000 or egg white diluted 1 in 50,000,000.

Specimens of giant frogs were exhibited by the Department of Zoology, Natural History Museum (Mr. C. Tate Regan). *Rana goliath*, from S. Cameroon, is the largest known frog, attaining a length of nearly 12 inches, without the limbs. *Rana guppyi*, from the Solomon Islands, is remarkable in that it feeds almost exclusively on crabs, which are swallowed whole.

Some results of researches on the biology of aphides, with particular reference to *Aphis rumicis*, were illustrated in the exhibit of the Entomological Department, Institute of Plant Pathology, Rothamsted (Dr. A. D. Imms and Dr. J. Davidson). Breeding experiments have shown the relationship between the agamic and gamic generations, and the appearance of winged and apterous forms; the changes associated with these phases are due to internal factors. Variations occur in the same species on different plant hosts.

Internal casts of a gigantic freshwater gastropod from Wealden Rocks, near Silver Hill, Hastings, were exhibited by the Department of Geology, British Museum (Natural History). Twenty-three whorls, including the body-whorl, are traceable, with a total length of 7 ft. 3 in. The affinities of the mollusc are probably with the Tiaridæ.

Astronomy was represented by exhibits from the Royal Observatory, Greenwich. Photographs with the 30-inch reflector were used to show a relation between the effective wave-lengths of stars and their spectral type. When a coarse grating is placed before an objective, short diffraction spectra are produced in the focus on either side of a central image, the distance between the diffracted and central images being a function of the wave-length of the light. This furnishes a convenient means for determining the colours of the stars as defined by the wave-length of maximum photographic intensity. A chart of variation of latitude at the observatory during 1911–1921 was also shown. The curve can be analysed into two principal components, one with a period of 432 days, and the other with a period of one year. The amplitude of the first component is about twice that of the second.

Sir William Bragg and Prof. W. L. Bragg exhibited a number of models, on a scale of $10^8 : 1$, illustrating crystal structure. By X-ray analysis, the size of the cell containing the unit of pattern of the crystal is found accurately. The distance between the centres of neighbouring atoms is also known and accurate models can be constructed which, in the case of organic crystals, are based on the principle that benzene and naphthalene molecules are frameworks of definite dimensions.

Prof. H. B. Baker gave a demonstration of the changes produced by prolonged drying on the boiling-points of liquids. Dried benzene does not boil when immersed in boiling water, and other liquids including mercury, bromine, alcohol, and ether show a rise in boiling-point which varies from 26° to 62° C. The surface tension also increases, indicating that the change may be due to increase in the size of the molecules.

The National Physical Laboratory had a number of exhibits. A precision bridge for platinum thermometry designed by Mr. F. E. Smith was shown by Mr. W. F. Higgins and Mr. F. H. Schofield. The resistances of the two variable arms of the bridge system used are of the order of 100 times that of the thermometer, so that brush contacts can be used without appreciable sacrifice of precision. The steps on the lowest dial correspond to 0·001° C. The Research Department, Woolwich, Radiological Branch, exhibited a metal X-ray tube of novel form, with an iron target. The tube is of the hot cathode type, and is constructed chiefly of metal, the insulation between the anode and the case being secured by a glass sleeve. Both the anode and the metal case are water-cooled. The tube is self-shielding, only a narrow pencil of X-rays escaping from an aluminium window. It is designed to give very soft radiations, and to run continuously with a heavy current. The Cambridge and Paul Instrument Company, Ltd., showed a micro-indicator for taking diagrams from high-speed engines. The vertical movement of the end of a small indicator piston deflects a strong triangular spring carrying a stylus which scratches a micro-diagram of a single complete cycle upon a disc of transparent celluloid. The actual size of the diagram is approximately 3 mm. base (time) by 2½ mm. height (pressure).

Mr. W. M. Mordey demonstrated some striking effects of alternating magnetism. Magnetic materials, including finely divided iron, nickel, cobalt, magnetite and specular hæmatite, show a steady movement or migration through or from a multiphase field in a direction opposite to that due to eddy currents. In a multiphase field vertical "planes of force" are formed, but there is no movement of finely divided aluminium nor lead shot. Water containing any of these materials may be driven uphill in a multiphase field, an effect which is probably due to surface-tension. The method can be applied to the concentration or separation of certain minerals, wet or dry (NATURE, April 29, p. 556).

During the course of the evening Lord Rayleigh gave an account of his recent spectroscopic investigations of the aurora borealis, with particular reference to its occurrence on ordinary nights in the South of England.

It is impossible in the space of a short article to do more than indicate some of the many interesting and important exhibits which were displayed. There were several novel pieces of physical and electrical apparatus which have not been mentioned, and the whole combined to form a noteworthy and interesting display.

Motor Headlights.

A DISCUSSION took place on the above subject at a meeting of the Optical Society on May 11. Mr. J. W. T. Walsh, of the National Physical Laboratory, in his opening paper, recalled that the design of headlights had been much discussed recently, for example, at meetings of the Illuminating Engineering Society from 1911 onwards. The problem resolved itself into a compromise between the needs of the motorist, who required a sufficiently powerful beam to distinguish objects in time to pull up or slacken speed, and the desire of the pedestrian or driver of approaching vehicles not to be dazzled by glare. In discussing the nature of glare, essentially a physiological problem, Mr. Walsh showed diagrams relating contrast sensibility of the eye and brightness, and the effect of obliquity of the bright source in the field of view. Attempts had been made to fix a "glare limit" for a field of a given brightness, and it was generally recognised that glare was largely a matter of contrast. The limitation of the powerful driving beam below a certain plane, so as to obviate intense light striking direct into the eyes of approaching persons, had been advocated and embodied in various codes, but it is recognised that, in addition to the main beam, moderate diffused general illumination is desirable. Requirements for headlights had been somewhat fully dealt with in American regulations. For instance, it had been prescribed that the illumination measured 100 yards away should not fall below a certain value, and in the latest specifications drafted by the American Illuminating Engineering Society minimum values for the main beam-candlepower, and maximum candlepower values at other angles (with the view of limiting glare), had been stated. Some polar curves, showing the distribution of light from typical modern headlights, were shown, a maximum candlepower of 5000 being attained in some cases. Another device for testing the power of the beam, intended to be applied on the road and where photometric measurements were impracticable, was the Royal Automobile Club standard disc, which comprised patterns of white lines on a black background, the requirement being that the patterns should be distinguishable by the available illumination at a specified distance from the car. The disc was referred to in the latest report of the Ministry of Transport Committee on Lights on Vehicles. It was generally agreed that legislation was a difficult matter but much could be done to improve conditions by making the fundamental principles of design well known.

In the ensuing discussion Commdr. T. Y. Baker (Admiralty Research Dept.) described a simple apparatus for measuring brightness, the object to be tested being viewed through a tube, and its brightness compared with that of a lamp emitting light down a side-tube.

Mr. Leon Gaster (Hon. Secretary of the Illuminating Engineering Society) remarked that the subject had been much discussed in various countries, not only by the Illuminating Engineering Society in the United States (as Mr. Walsh had mentioned) but in recent proceedings of the German Illuminating Engineering Society. At the first technical session of the International Illumination Commission in Paris last year it was resolved to appoint an international technical committee to deal with the problem. The Illuminating Engineering Society in this country had formed a joint committee on motor-headlights, and he gladly took the opportunity of inviting the Optical Society to nominate a representative. Mr. Gaster also pointed out that regulations prescribing a certain illumination at a specified distance ahead of the car depended essentially on the speed of driving. The distance was presumably based on the length of road in which a car driving at 20 miles an hour could pull up. With the removal of the speed limit such requirements might need revision.

The Chairman (Mr. Whipple), having thanked Mr. Gaster for the invitation conveyed to the Optical Society to appoint a representative on the Illuminating Engineering Society joint committee, called upon Mr. J. S. Dow to continue the discussion. Mr. Dow pointed out that glare was mainly a matter of contrast and should therefore be considered in relation to street lighting. He believed that in certain cases a device had been employed to direct light on the front of a car, enabling its outline to be seen more clearly and diminishing the contrast between the brightness of the headlight and its surroundings. It had also been suggested that glare depended to some extent on colour, and that a slight yellow tint, though involving some loss of light, was preferable in this respect, as well as giving somewhat better definition of distant illuminated objects.

Sir Wm. Barrett, in the absence of Sir Howard Grubb, described and demonstrated the Grubb headlight, of which he had had favourable personal experience. The primary principle now usually aimed at in modern headlights, is that the main beam should be confined below a height of 3 feet above the roadway, so that the beam did not shine in the eyes of persons approaching, a milder and more diffused light being distributed outside this limit. The original headlight utilised two "D"-shaped lenses separated by a strip of grooved glass to effect this division, but more recently the design has been improved, two horizontal strips being inserted, and the arrangement of the lenses has also been modified. Sir Wm. Barrett presented a table summarising the requirements of the code for headlights adopted in Massachusetts, including a maximum beam-candlepower of 5000, and showed that these had been complied with in this form of headlight.

In the ensuing discussion a great variety of headlights was demonstrated. Generally speaking, the aim was to provide a powerful beam, but to restrict the candlepower in directions above a certain horizontal plane. It was evident, however, that the distribution of light effected by the various devices differed considerably. One ingenious device comprised the use of a supplementary concave reflector covering the upper half of the headlight whereby light-rays in the upper hemisphere were directed back on to the main reflector and added to the main beam. Various devices to assist the provision of suitable side-illumination, in addition to the main beam, were also described. Thus in the Zeiss headlight there is a special annular reflecting surface which furnishes diffused illumination on either side of the car. Another feature is the use of a Bowden wire arrangement to enable the motorist to cut out the dazzling effect of the headlight while retaining sufficient light for a shortened track. This effect can be produced at any time, and is recommended for use in the well-lighted streets of large towns, where there is considerable traffic.

One other device that may be mentioned is the Kent glare screen, which consists of a small plate of coloured glass, which can be attached to the windscreen so that the driver, by slightly moving his head, can bring an opposing headlight within the field covered by this screen and thus reduce its dazzling effect.

Some Post-War Problems of Transport.

SIR JOHN ASPINALL'S long and unique experience in transport problems renders his "James Forrest" lecture—delivered at the Institution of Civil Engineers on May 2—of importance to the general public, all of whom are interested in passenger traffic and affected by the cost of the carriage of goods.

Sir John Aspinall dealt first with London passenger traffic. In the early days of the lay-out of railways the short distance passenger was scarcely considered, and it was only by degrees that his demand for greater facilities was met. Other lines of way have been added, and the notable addition of the tubes has been very effective. Travel has been helped also by attention to details. The modern station with its escalators is a vast improvement on the older types with long and tortuous passages, and plain, well-lighted directions enable passengers to find their way easily. In the carriages, high backs to the seats prevent vacant seats being seen; strap-hanging is preferable to pillars, which are apt to produce blockages. The necessity of quick loading and unloading of a car means that the doorway and platform arrangements have to be considered. It is a matter of common knowledge that getting into and out of a carriage during the rush hours at present is an exceedingly trying operation. Sir John Aspinall suggests the use of three platforms, two outer and an island platform. Passengers from both trains alight on the island platform and the trains are loaded from the outer platforms. This plan should be very effective in separating the streams of passengers. Proposals have also been considered by the tube companies for deeper tubes with fewer stations, suitable for quicker long distance travel.

The excellent reports and maps prepared by the London traffic branch of the Board of Trade indicate that future provision for the growing population will require to be made towards the north-west and south-west, both of which have much blank travel space on the map. Admirable as may be the organisation which cuts down time spent in the steam operation of suburban trains, it would appear that London traffic must henceforward rely on electrification to make more frequent service possible.

Traffic on the roads follows the same lines as the railway traffic. Here the motor bus helps greatly. In 1921 the London General Omnibus Company handled 761,250,000 passengers, which is nearly half the number dealt with by all the railways in Great Britain. The total passenger mileage on all the railways was 227,397,353, and the buses ran 87,000,000 miles, approximately one-third that of the railways. The improvement of the motor bus has been so great that it is safe to assume that the much more expensive tramway system will not be greatly extended.

Notwithstanding the help of the most modern buses, the extension of railway facilities in London is urgent. The engineering world has not been backward in proposing new means of dealing with London traffic. Most of the schemes prepared before 1903 represent an enormous waste of money, not because they were bad, but because of our methods of private bill legislature, which often result in the defeat of well-planned proposals on grounds which subsequent events showed to be unsound. Sir John Aspinall does not despair of some first-rate scheme being adopted for future gradual development if it were in the first instance considered and proposed by a strong committee of those who are engaged in handling London traffic to-day, and then legalised. Hitherto so much harm has been done by dealing with this problem in bits that it becomes the more desirable to deal with it as a whole.

There has been great architectural objection to the continued existence of certain railway bridges over the Thames. On the other hand, the daily number of people crossing these is much larger than could pass over road bridges. Hence their abolition would inconvenience the travelling public. The objection on account of unsightliness is legitimate, and can be avoided. A well-known engineer has shown how a double-decked bridge can be constructed at Charing Cross with all those architectural features which our architect friends desire. In this bridge the railways cross at the same level as at present; the roadways are at a higher level and descend with easy gradients on both sides of the river.

So far as we have gone, it appears to be true that passenger traffic facilities have never been in advance of London requirements.

Sir John Aspinall gives strong evidence in favour of long distance electrification on main-line railways. The train capacity of any railway and particularly of any terminal station is vastly increased by electrification, and thus the capital cost of extensions and widenings can be postponed for years. Shunting is very costly; of a total of 288,000,000 freight engine miles run in Great Britain, half was on remunerative work and 117,000,000 miles on shunting. The ultimate ownership of all wagons by the railway companies—thus cutting out the private owner—will eliminate much shunting expenditure. Much economy may also be anticipated from the new group system. Sir John Aspinall has also something to say about local rates. There are many country districts through which railways run but have no stations and therefore are not road users, where the railways have to pay from 5 to 90 per cent. of the parish rates. The equity of the case appears to demand that those who do the damage to the roads should pay the cost. On the Great North Road the "tons per yard width of road per day" was 77·7 in 1912 and 300·8 in 1920, and of the latter figure 51·5 per cent. was due to heavy motors and tractors, for which the figure was 16·9 per cent. in 1912. Goods transport by road involves 300,000 vehicles at present, and road maintenance costs 50,000,000*l.* per annum.

There is not a great deal of water power available in this country for the production of electric current, and we must still largely rely on coal.

There seems to be much misunderstanding as to the merits of canals. The fact is, however, that the days of the small barge canal are gone. The greater canals, which permit of the passage of large cargo steamers, are on an entirely different basis. Sir John suggests the conversion of disused canals into roads, which of course would be level excepting where there are locks.

Many modern writers have pressed that civil aviation should receive considerable national assistance, but the same methods of gradual and persistent investigation which have been applied for so many years to the ships of the sea must be applied to the ships of the air. There will probably be common agreement that at no time in the history of this country has national transport been so intimately connected with the necessities of national defence.

Colston University Research Society.

BRISTOL is peculiarly fortunate in possessing a unique organisation for the encouragement of research at its University. Originally founded in 1899 and named in honour of the famous philanthropist, Edward Colston, its funds were at first applied to the support of the then University College in connection with its proposed expansion to a University. This accomplished, the Colston University Research Society undertook the distinctive function of supporting research work within the University, and since 1910 some 3700*l.* have been raised and applied to scientific investigations, which in most cases could not otherwise have been carried out; these include contributions to medicine, engineering, and to the general advancement of knowledge.

The essential importance of scientific research, realised a generation ago by Germany, was brought prominently before every citizen during the Great War. The serious industrial difficulties of the past two years have brought home to most people the fundamental interdependence of production and prosperity. For cheap production we need to-day increased invention in every direction. Modern invention is based on scientific research, and it is to the development of scientific research that all who are engaged in industry must look for the permanent revival of British industrial supremacy. Every process we employ, every device and invention of which we take daily advantage, is the result of some former, maybe forgotten, research. Enlightened opinion recognises that some seed corn must be returned if the future is to repeat the successes of the past. It is a sign of the times that men should now rally to the support of the most essential function of our universities.

The Colston University Research Society consists of members of the public and of industrial firms of Bristol and the west of England who subscribe the necessary research funds. On May 23 each year the annual dinner is held, at which the City of Bristol, the Society of Merchant Venturers, and the Bristol Chamber of Commerce are represented. The chief guests include one or more distinguished educationists or investigators. This year the Minister of Education and Prof. G. Elliot Smith were two of the invited guests of the evening.

The society affords an opportunity for every citizen to give direct support to research work for the advancement of knowledge, and similar organisations might with great advantage be established in all university towns. The society accepts the term "Research" in the widest sense, and looks forward to the time when research work in the Arts side may also receive assistance through the society from the community at large.

A new departure under this year's president, Mr. Ernest Walls, is the establishment of Colston research fellowships, whereby it is hoped that the University may render service to local industries. Industrial firms are invited to endow post-graduate research fellowships at the University, the fellow receiving 150*l.* per annum. The fellowships may be earmarked to a particular faculty or branch of research or to a particular research problem. In the last case, this is subject to the approval of the professor agreeing to supervise the work, and if it is an industrial problem the donor bears all expense. A form of agreement between the University, the donor, and the research fellow may be required.

The donor of a fellowship will have access to the research work and will receive the results of the work twelve months prior to publication. Five firms have already undertaken to endow fellowships, three in chemistry, one in engineering, and one not earmarked. These fellowships should serve to link the University more closely to the life of the city without sacrifice of academic freedom, and, apart from the advantages accruing to the firms, will undoubtedly lead to permanent industrial appointments for some of the best graduates.

It will be interesting to see whether this plan may not suit the conditions of the British Universities better than the well-known system of industrial fellowships of the Mellon Institute in the United States.

A record annual collection announced at the Colston University Research dinner at Bristol on Tuesday amounted to 939*l.* 1s., the largest individual amount being 25*l.* In addition, 1100*l.* were collected for Colston Research Fellowships.

Active Hydrogen.

IN a short communication by Mr. Y. Venkataramaiah, read before the Science Association, Maharajah's College, Vizianagram, S. India, in January 1920, and published in the Proceedings of the Association for July 1921, the formation of active hydrogen by passing hydrogen through an ozoniser is described. The active form combined with sulphur and phosphorus at the ordinary temperature. In a previous communication to NATURE (of September 9, 1920, p. 46) the same author described an active form of hydrogen, formed by the explosion of oxygen with excess of hydrogen, which reduced potassium permanganate solution rapidly at room temperature. These discoveries were, apparently, made independently of those of Wendt and Landauer (Journal of the American Chemical Society, 1920, 42, 920), who obtained active hydrogen by the action of the corona discharge on hydrogen at low pressure, and by the action of α-rays on hydrogen.

The American authors now describe (Journal of the American Chemical Society, March 1922) the production of active hydrogen by the action of the silent discharge (as previously described by Venkataramaiah), by the action of a high-frequency Tesla discharge, and by the action of thermionic emission, on hydrogen. In all cases only small amounts of active hydrogen are formed, and it is rapidly decomposed. Since it is formed with contraction, and is condensed in liquid air, the authors consider it to be represented by the formula H_3, although they give no evidence for this particular composition. They do not accept the suggestion, made by E. C. C. Baly ("Annual Reports of the Chemical Society," 1921), that their product is identical with the purely hypothetical "iso-hydrogen" of Harkins, which, although represented by the symbol H_3, is supposed to consist of a single atom with an atomic weight of 3 units.

This use of chemical symbols with an unusual meaning, as in the similar case of the isotopes of chlorine, which are often described as Cl_{35}, etc., is, in fact, most confusing, and it is very desirable that some less objectionable notation should be adopted. We suggest that the symbol Cl(35), for example, which could be adapted to formulæ such as Cl(35)Cl(37), would meet the case.

University and Educational Intelligence.

Cambridge.—The Council of the Senate has approached the President of the Board of Education, stating that the immediate appointment of a Statutory Commission for Cambridge would be welcome on the understanding that the University and Colleges would have an opportunity of bringing their views on the detailed recommendations of the present Commission before the Statutory Commission.

A welcome bequest to the Fitzwilliam Museum from the late Mr. S. G. Perceval of Trinity Hall is announced. His collection of pictures, books, manuscripts and objects of art at present on loan to the museum is now bequeathed to the Museum, and an estate with an income of 400*l.* a year.

Mr. W. W. Rouse Ball of Trinity College offers the University the sum of 500*l.* to constitute a Trust Fund for the provision of occasional lectures dealing either with some particular development of mathematics or application of mathematics to science.

Dr. G. P. Bidder of Trinity College has offered 5000 lire, subject to equal help from the Balfour Trustees, in order that a research student may be sent to the Stazione Zoologica at Naples for six months in the coming autumn.

Dr. E. Lloyd Jones, Downing College, has been reappointed demonstrator of medicine. It is proposed to appoint Mr. E. A. Milne, Trinity College, university lecturer in astrophysics.

Mr. B. K. Martin, Magdalene College, has been nominated to hold the Princeton Visiting Fellowship for the year 1922–23, and there has been recently notified a visiting scholarship at Yale University to be held preferably by a man who has not completed his course at Cambridge but intends to return to Cambridge at the end of a year at Yale. The Joseph H. Choate Memorial Fellowship at Harvard University will also shortly be filled.

A grant of 150*l.* is to be made to Mr. J. M. Wordie, St. John's College, towards the expenses of an expedition to Greenland for work in geology, botany, zoology, and ethnography.

Leeds.—The Council of the University has elected Dr. Albert Gilligan to the chair of geology. Dr. Gilligan, who was educated at Wolverhampton Grammar School and University College, Cardiff, has been lecturer in economic geology and reader in petrology in the University. He has published important researches on the Carboniferous rocks of the north of England and upon the petrography of the Millstone Grit in Yorkshire, and has been awarded the Murchison Fund by the Royal Geological Society. Dr. Gilligan succeeds Prof. P. F. Kendall, and the Council of the University has placed on record its appreciation of the value of the work performed by Prof. Kendall during his thirty years' connection with the Yorkshire College and the University of Leeds.

Mr. S. Barratt has been appointed assistant lecturer and demonstrator in chemistry. Mr. Barratt was educated at Clifton College and at Balliol, Oxford, where he obtained a first-class in the Honours School of Chemistry and a research scholarship which enabled him to work for two years with Prof. T. R. Merton. He was joint author with Prof. Merton of a paper on "The Secondary Spectrum of Hydrogen," which formed the Bakerian Lecture of the Royal Society delivered on March 9 last.

Mr. Alexander Hamilton Thompson, reader in mediæval history in the University of Durham (Armstrong College), who has edited the *Archæological Journal* since 1919 and has published work on Yorkshire antiquities, including the Ecclesiastical History of the county contributed to the "Victoria County History," has been appointed reader in mediæval history.

The following appointments have been made from the staff of the University:—Mr. W. Godden, for a number of years lecturer in agricultural chemistry and advisory chemist in agriculture, to be head of the Biochemical Department of the Rowett Institute for Research in Animal Nutrition at Aberdeen; Mr. D. B. Johnstone-Wallace, district lecturer in agriculture, to be agricultural organiser for Devonshire.

Queen's College, London, which was founded by F. D. Maurice and other King's College professors in 1848, and incorporated by Royal Charter in 1853, was the first institution devoted to the higher education of women. It represents, therefore, the beginning of a movement which has enlarged the sphere of women's activities far beyond anything contemplated in the middle of the nineteenth century. All who have broad and liberal conceptions of education appreciate the value of the pioneer work done by the College and the distinguished men associated with it, such as Charles Kingsley, Edward Forbes, D. T. Ansted, H. G. Seeley, Rev. G. Henslow, W. B. Carpenter, Sterndale Bennett, W. H. H. Hudson, J. D. McClure, and W. A. Miller, to mention only a few scientific leaders whose names are among those of past professors. Throughout its existence the College has stood for independence and true learning, and all are now gathering fruit from the tree which it planted. The appeal which has just been made for the sum of 20,000*l.* to enable the College to purchase the adjoining house in Harley Street, and thus extend and consolidate its activities, ought, therefore, to meet with a ready and generous response. "At no time in our history," says Lord Askwith, chairman of the Appeal Committee, "has it been so important that women should be able to have guidance in their new powers and keen desire for knowledge"; and we hope that a college which has done so much to realise the highest physical, intellectual, and moral ideals will be provided with the resources desired to continue its valuable work. The appeal has the support of Mr. H. H. Asquith and Sir James Frazer among others, and it is one which we particularly commend to all who are interested in the place of women in a reconstructed world. Donations should be sent to: The Queen's College Extension Appeal Fund, London County Westminster and Parr's Bank, Ltd., Cavendish Square, London, W.

The Board of Education has approved an arrangement whereby students of University College, Reading, receiving grants under the Board's Regulations for the Training of Teachers, will be permitted, if suitable for a course of agricultural study, to take the London University External B.Sc. degree course in agriculture as an alternative to a course in arts or pure science. Students wishing to follow this course must enter the training department of the College for a course of three years, which, if successfully completed, enables them to obtain the degree and also to secure recognition by the Board of Education as Certificated Teachers. The training in teaching ordinarily proceeds concurrently with the degree work throughout the three years, but a student who has passed the Intermediate Science (Agriculture) examination before admission to the College devotes the first two years to the final degree course and the third year to a post-graduate course in the theory and practice of teaching. Further particulars of the course of training can be obtained from the Tutorial Secretary of University College, Reading.

Calendar of Industrial Pioneers.

May 28, 1831. Henri Grégoire died.—Famous as an ecclesiast and a politician, Grégoire played a conspicuous part in the great events of the French Revolution, and through him the Convention sanctioned the decree of October 10, 1794, for the formation of the Conservatoire des Arts et Métiers and its installation in 1797 in the old priory of Saint-Martin-des-Champs. The Conservatoire is one of the most important scientific and industrial museums in the world.

May 29, 1864. Georg Bodmer died.—A mechanical inventor who greatly aided the progress of manufacturers, Bodmer was born in Zurich in 1786. He introduced breech-loading cannon and percussion shells, improved cotton-spinning machinery, and assisted in the construction of the Austrian railway over the Semmering.

May 31, 1831. Sir Samuel Bentham died.—Born May 11, 1757, Bentham was the elder brother of Jeremy Bentham the writer. Apprenticed to the master shipwright at Woolwich Dockyard, he studied naval architecture, and, after serving for some years under the Russian government, in 1795 was engaged by the British Admiralty to introduce machinery into the dockyards. He invented the caisson method of closing docks, designed steam dredgers, and assisted Brunel in his block-making machinery.

May 31, 1898. Sir Robert Rawlinson died.—Trained by his father, who was a builder in Lancashire, Rawlinson worked on the London and Birmingham railway under Robert Stephenson, became engineer to the Bridgewater Trust, and from 1848 to 1888 held the important post of chief engineering inspector to the Local Government Board. In 1894 he served as president of the Institution of Civil Engineers.

June 1, 1835. Thomas Charles August Dallery died.—One of the pioneers of screw propulsion, Dallery was an organ builder of Amiens. In 1803 he constructed a steam boat driven by a screw, or "escargot" as he called it, and placed it upon the Seine at Bercy. Imperfections in the machinery, which included a tubular boiler, led to the abandonment of the project.

June 2, 1891. Sir John Hawkshaw died.—A native of Leeds, where he was born in 1811, Hawkshaw gained experience on some of the northern railways and then became a consulting engineer in London. He was responsible for the stations and bridges at Cannon Street and Charing Cross, and was engineer to the East London Railway and the Great Severn Tunnel. With Brunlees he was connected with the scheme for a tunnel beneath the English Channel, and with Barlow he completed the Clifton Suspension Bridge. He was a fellow of the Royal Society and served as president of the Institution of Civil Engineers and of the British Association.

June 2, 1895. George W. Brown died.—Known in America as "the father of the corn planter," Brown was born in New York State, October 29, 1815. He began life as a farmer, then became a carpenter and assisted in the building of the second railway in New York. He brought out his first corn planter in 1851, and by 1866 there were 3000 in use. The invention and development of the corn planter was largely responsible for the prosperity of the middle west of America.

June 2, 1910. Edward Locher-Freuler died.—A celebrated Swiss engineer, Locher erected factories, water works, railway bridges, and power stations, and in middle life joined the firm of Brandt, Brandan and Co. With his partners he was responsible for the construction under the Alps of the Simplon Tunnel, 12½ miles long, which was opened on June 1, 1906.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, May 11.—Sir Charles Sherrington, president, in the chair.—Lord **Rayleigh**: (1) A photographic spectrum of the aurora of May 13-15, 1921, and laboratory studies in connection with it. A photographed spectrum of the aurora on the night of May 14, 1921, shows the negative bands of nitrogen in detail, and the green aurora line which, however, is subordinate. With atomic ray excitation of nitrogen in the laboratory, and better, in the narrow positive column (capillary tube) at low pressure, the development of the negative bands can be imitated, but other nitrogen spectra (line spectrum and second positive band spectrum) persistently appear in addition. The cathode ray spectrum is free from the latter, but the negative bands produced are not developed like those in the aurora, the intensity being much more concentrated in the first band of each group. Hard and soft cathode rays behave alike in this respect. Assuming that helium is the main constituent of the atmosphere above 130 kilom., as the theory of diffusion indicates, then it is difficult, on the hypothesis of positive ray excitation, to explain its absence from the spectrum of this particular aurora, which at Christiania reached to 470 kilom. Experiments on artificial mixtures indicate that it should be visible. With cathode ray excitation, this difficulty would be lessened, but the different development of the nitrogen bands remains.—(2) A study of the presence or absence of nitrogen bands in the auroral spectrum. Spectra of the "Northern Lights" taken in Shetland are compared with spectra of the ordinary night sky at Terling near London. Most of the Shetland spectra show nitrogen bands. None of the ordinary Terling spectra show these bands, though, owing to the long exposure given, the Terling plates show the green aurora line as strongly, or more strongly, than the Shetland spectra. On the occasion of the great magnetic storm and world-wide auroral display of May 13-14, the nitrogen bands were strongly developed at Terling.—C. **Chree**: The 27-day period (interval) in terrestrial magnetism. There is a tendency in terrestrial magnetism for disturbance to follow disturbance, and calm to follow calm, after an interval which does not depart much from 27 days. The absolute daily range of declination at Kew Observatory from 1858 to 1900 and the international "character" figures from 1906 to 1920 both show the phenomenon. Generally, it is more clearly exhibited in years when sun spots are few in number or are situated in low solar latitudes. The season of the year seems to have little, if any, influence.—M. **Barker**: On the use of very small Pitot tubes for measuring wind velocity. The finite pressure in a one-sided Pitot tube for infinitely small openings is comparable with that at the nose of a sphere, of diameter equal to the breadth of the opening, placed in a stream moving with a velocity equal to that at the centre of the pitot opening. This indicates a breakdown in the $p=\frac{1}{2}\rho v^2$ law for Pitot tubes, when the dimensions of the pitot are very small or the velocity very low, ρ being the density and v the velocity of the fluid and p the pressure difference. The value of rv/ν below which the $\frac{1}{2}\rho v^2$ law ceases to hold, r being the radius of the circular Pitot tube and ν the kinematical viscosity of the fluid, has been determined. For values of $rv/\nu<30$, $p/\rho v^2$ is greater than $\frac{1}{2}$; below this value there is a viscosity effect in the form of an additional pressure comparable, as before, with that at the nose of a certain sphere.—E. T. **Paris**: On doubly resonated hot-wire microphones. The properties of

double resonators for use with hot-wire microphones in order to increase sensitivity and also, if desired, to widen the range of response were investigated. Two types of resonator were dealt with: (a) The "Boys double resonator," consisting of a "stopped pipe" in series with a Helmholtz resonator; and (b) the "Helmholtz double resonator," consisting of two Helmholtz resonators in series.—J. C. **McLennan** and D. S. **Ainslie**: On the structure of the line $\lambda = 6708$ Å of the isotopes of lithium. A vacuum arc in the vapour of the metal together with Lummer plates and a 30-plate échelon grating crossed with a Lummer plate to effect the resolution were used. With strong arcs, $\lambda = 6708$ Å consists of two doublets, with a separation of the doublet components of 0·128 Å and 0·165 Å respectively. The mean displacement of the two doublets is 0·32 Å, which is 3·4 times that demanded on Bohr's theory for isotopes of lithium having atomic weights 6 and 7. Merton and also Aronberg in studying $\lambda = 4058$ Å, in the spectrum of ordinary lead, and in that of lead having a radio-active origin, found that the observed difference in wave-length was between 80 and 90 times as great as the difference to be expected from Bohr's theory. With both lead and lithium, in what would appear to be isotopic spectral displacements, the value found by observation is about the atomic number times the value obtained by calculation on the basis of Bohr's theory.

Zoological Society, April 25.—Sir S. F. Harmer, vice-president, in the chair.—A. **Loveridge**: Lions at their kill.—R. J. **Ortlepp**: A new species of the nematode genus Œsophagostomum from the rodent *Xerus setosus*.—R. **Broom**: On the persistence of the mesopterygoid in certain reptilian skulls.—C. F. **Sonntag**: On the anatomy of the drill (*Mandrillus leucophæus*).—A. **Loveridge**: New reptiles from Tanganyika Territory.—Miss L. E. **Cheesman**: Observations on the land-crab, *Cardisoma armatum*, with especial regard to the sense organs.

May 9.—Dr. A. Smith Woodward, vice-president, in the chair.—C. F. **Sonntag**: The comparative anatomy of the tongues of the Mammalia.—VII. Cetacea, Sirenia, and Ungulata.—D. W. **Devanesen**: Notes on the anatomy of *Cacopus systoma*, an Indian toad of the family Engystomatidæ.—E. A. **Elliott**: Monograph on the family of the Stephanidæ (Hymenoptera).

Linnean Society, May 4.—Dr. A. Smith Woodward, president, in the chair.—H. **Downes**: A relic of Henry Lyte's library. The volume consists of two works of Antoine Mizauld, the French Physician (1520–1578), "Alexikerus" and "Nova et Mira Artificia," bound together (Paris, 1564). It contains Henry Lyte's autograph, and various notes. At the end of the volume are two pages of MS. notes, mostly medical definitions or short descriptions of diseases. Henry Lyte was the translator of Dodoen's Herbal, the first edition of the translation being dated 1578. He was a member of the ancient family of Lyte of Lytes Cary, in Somersetshire, and according to Pulteney he became a student of Oxford in 1546.—J. Lloyd **Williams**: The life-histories of Laminaria and Chorda. Two kinds of gametophytes, producing eggs and antherozoids respectively, exist in the Laminariaceæ. Cultures of Laminaria three weeks old, and of Chorda three or four months old, almost invariably show the presence of two kinds of multicellular germlings, one large celled, the other consisting of cells many times smaller. The liberation of the sexual cells and the process of fertilisation have now been observed. Drew's observation of the sexual nature of the "Zoospores" was incorrect. The organisms described by him could not have been the zoospores of Laminaria, but must have been colourless monads. The Laminariaceæ thus show distinct alternation of generations: the plant is the sporophyte; reduction of chromosomes takes place in the sporangium; there are two kinds of gametophytes—a male and a female—and the difference in size between the generations is exceedingly great. The sporophyte may be gigantic, as compared with other algæ, whereas the gametophyte is microscopically small.

Royal Anthropological Institute, May 9.—Dr. W. H. R. Rivers, president, in the chair.—Capt. M. W. **Hilton-Simpson**: Ethnographical researches among the Berbers of the Aures Mountains in South-East Algeria. Physical features make the Aures massif a cultural island, in which there are many instances of the survival of ancient crafts among the Shawía, as these Berber tribes are termed. A method of manufacturing olive oil, the existing system of corn milling, and perhaps, the "waterclock" for measuring times of irrigation, evidently crept into the massif in Roman times, to remain unaltered to this day. Some arts are much older still, as witness the wheelless manufacture of pottery, which probably dates back to about 900 B.C. Being accompanied by his wife, the author was able to observe in detail the occupations of the women. Their weaving is of a very archaic kind. Traces of pre-Islamic cults can still be observed among the Shawía which, though individually slight, seem to point to a survival of the worship of a great goddess of motherhood and fertility.

DUBLIN.

Royal Irish Academy, May 8.—Prof. Sydney Young, president, in the chair.—H. H. **Poole**: Isotopes. An account was given of the discovery of the existence of isotopes among the radioactive and later among non-radioactive elements. The bearing of these discoveries on our views as to the nature of the atom was described, and the vast store of energy implied by the deviation of hydrogen from the whole number rule was mentioned as a possible future source for human use, and as a source of solar radiation.

PARIS.

Academy of Sciences, March 1.—M. Emile Bertin in the chair.—P. **Painlevé**: The classical and the Einstein theory of gravitation. A statement of the postulates of the classical theory of mechanics and of the modifications implied in the Einstein theory.—G. **Mittag-Leffler**: Gauchy's theorem on the integral of a function between imaginary limits.—J. **Andrade**: The mechanical problems of regulating springs in chronometry.—P. **Vuillemin**: Relations between the chlamydospores and the mycelian loops.—E. O. **Lovett**: The generalisation of a problem of Sophus Lie in the geometry of contact transformations.—A. **Séguin**: An automatic multiplying machine.—J. **Chazy**: The astronomical verifications of the theory of relativity. The following consequences are deduced: If the radius of the universe, supposed cylindrical or spherical, is of an order greater than 1000 years of light, the correction discussed in this note of the longitudes of the planetary perhelia is impossible to observe, but if the radius is of the order of 1000 years of light, the correction considered is nearly comparable with the actual observations, but it is impossible that the radius should be of the order of 100 years of light or less.—J. **Trousset**: The laws of Kepler and the relativist orbits. The deviation between the Einstein and Kepler orbits is of the order of one kilometre, and this, at the planetary

distances, is seen from the earth at an angle of one-millionth of a second of arc.—M. **Painlevé**: Remarks on the two preceding communications.—P. **Fatou**: The movement of a planet in a resisting medium.—G. **Guillaumin**: The equilibrium of a talus in coherent earth.—P. **Dienes**: The connection of the tensorial field.—M. St. **Procopiu**: An electro- and magneto-optical effect in liquids holding metallic powders in suspension. All liquids containing fine metallic powders in suspension show negative double refraction both in a magnetic and in an electric field. Thus double refraction does not disappear at once when the field is suppressed; there is a lag of about three minutes, except in the case of mercury, in which the double refraction disappears almost instantaneously.—E. E. **Blaise** and Mlle. **Montagne**: The action of thionyl chloride on the α-acid alcohols. Thionyl chloride and glycollic acid give two main products: chloracetyl-glycollic chloride, $CH_2Cl.CO.O.CH_2.COCl$, and the chlorosulphite, $Cl.SO.O.CH_2.COCl$. The latter decomposes readily on heating into sulphur dioxide and chloracetyl chloride.—E. **Grandmougin**: The quindolines.—C. **Deguide** and P. **Baud**: A new method for the industrial manufacture of baryta for the treatment of sugar molasses. Barium carbonate and silica, both in a very fine state of division, are heated together at a temperature of 1300° C. Subsequent lixiviation with water gave from 78 to 81 per cent. of barium hydrate, $Ba(OH)_2.8H_2O$.—L. **Semichon**: The composition of wine lees.—L. **Royer**: The inversion of the rotatory power in anisotropic liquids.—H. **Joly**: The presence of transported scales or fragments in the Celtiberic chain. (Provinces of Saragossa, Logrono, and Soria, Spain.)—P. **Russo**: The geological constitution of the territory of the Hauts Plateaux and of Figuig (eastern Morocco).—H. **Lagotala**: The chronology of the Quaternary and the Cotencher excavations.—C. **Corroy**: The Neocomian and Albian reptiles of the Paris basin.—P. **Bugnon**: The bifurcated ramification in the cotyledons.—R. **Souèges**: The embryogeny of the Rosaceæ. The last stages of the development of the embryo in *Geum urbanum*.—A. **Labbé**: The *rôle* of the alkalinity of sea water in heterogeneous impregnations.—W. R. **Thompson**: Theory of the action of insect-destroying parasites. The mathematical formulæ of cyclic parasitism.—L. **Mercier** and R. **Poisson**: *Haplosporidium Caulleryi*, a parasite of *Nereilepas fucata*.

BRUSSELS.

Royal Academy of Sciences, May 2.—M. A. Lameere in the chair.—Cl. **Servais**: The geometry of the tetrahedron (V.).—Th. **De Donder**: On the theorem of Nernst.—L. **Godeaux**: On the rational correspondences between two surfaces of one kind.—G. **Fournier** and P. **Pruvost**: Discovery of a new fish in the black marble of Denée.—D. **Tits**: The exciting factors for germination in a fungus, *Phycomyces nitens*.

Diary of Societies.

FRIDAY, MAY 26.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Sir Thomas W. Arnold: Indian Painting and Muhammadan Culture (Sir George Birdwood Memorial Lecture).

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Dr. F. W. Aston: Atomic Weights and Isotopes (Lecture).

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section) (Annual General Meeting), at 5.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—J. C. Rennie: Engineering Appointments and how to get them.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.—Dr. R. Dudfield: Reforms needed in the Notification of Tuberculosis.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. W. E. Dalby: The Internal Combustion Engine: Its Influence and its Problems.

SATURDAY, MAY 27.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Hugh Allen: Early Keyboard Music (1).

MONDAY, MAY 29.

ROYAL GEOGRAPHICAL SOCIETY (Anniversary Meeting) (at Æolian Hall), at 5.30.—Presentation of Royal Medals and other awards; Presidential Address; Annual Report; Election of Officers and Council.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—W. Harvey: Colour in Architecture.

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Institution of Mechanical Engineers), at 8.—Sir George Beilby: Structure of Coke: Its Origin and Development.

TUESDAY, MAY 30.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Percy Sykes: Twenty-five Years' Travel in Persia.

ROYAL PHOTOGRAPHIC SOCIETY (Lantern Meeting), at 7.—E. J. Bedford: Wild Flowers.

FELLOWSHIP OF MEDICINE (at Royal Society of Medicine), at 5.—Sir W. Arbuthnot Lane, Bart.: Fractures.

WEDNESDAY, MAY 31.

ROYAL SOCIETY OF ARTS, at 3.—L. Haward: The Manchester Art Gallery and the Problem of Provincial Collections.

THURSDAY, JUNE 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Very Rev. Dean Inge: Theocracy (2). The Mediæval Idea.

ROYAL SOCIETY, at 4.30.—Prof. T. H. Morgan: The Mechanism of Heredity (Croonian Lecture).

LINNEAN SOCIETY OF LONDON, at 5.—Prof. A. C. Seward: Hooker Lecture.

JUNIOR INSTITUTION OF ENGINEERS (at Institution of Electrical Engineers), at 7.30.—Sir Eric Geddes: Fourth Canet Lecture

CHEMICAL SOCIETY, at 8.—J. S. Buck and I. M. Heilbron: The Reactivity of Doubly-conjugated Unsaturated Ketones. Part III. Unsymmetrical Hydroxy- and Methoxy-derivatives.—J. S. Buck and I. M. Heilbron: Phanopyryllium Salts of Distyryl Ketones. Part I.

FRIDAY, JUNE 2.

DIESEL ENGINE USERS' ASSOCIATION (at Institution of Electrical Engineers).—H. F. P. Purday: Marine Diesel Engines.

SATURDAY, JUNE 3.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Hugh Allen: Early Keyboard Music (2).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, MAY 26.

BIRKBECK COLLEGE, at 6.—Dr. E. J. Russell: Recent Work with regard to the Influence of Soil Conditions on Agriculture (3).

MONDAY, MAY 29.

UNIVERSITY COLLEGE, at 5.—A. T. Walmisley: Groynes and Sea Defence Works.

TUESDAY, MAY 30.

KING'S COLLEGE, at 5.30.—C. E. M. Joad: Vitalism Restated (1). The Reduction of Ethics to Psychology.—Dr. D. Subotić: Influence of Geography on the Economic Conditions of Jugo-Slavia (1).

WEDNESDAY, MAY 31.

KING'S COLLEGE, at 5.—Dr. A. Harker: Tertiary Igneous Action in Britain (3).

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. J. Babinski: Des Reflexes de Défense. (In French.)

SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. R. A. Nicholson: The Idea of Personality in Sufism (3).

UNIVERSITY COLLEGE, at 5.15.—Dr. D. H. Scott: The Early History of the Land Flora (6);—at 6.30.—Miss Mildred Swannell: Individual Work and Dr. Montessori.

THURSDAY, JUNE 1.

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 5.—Sir A. Cruickshank Houston: The Purification of Water.

SATURDAY, JUNE 3, 1922.

British Fine Chemicals.

DURING the period of twenty years preceding the war, it was a frequent complaint among organic chemists that there did not exist in this country a firm resembling Kahlbaum or Schuchardt, from which it would be possible to obtain, at short notice, large or small quantities of those organic compounds, both common and obscure, required for the prosecution of research. The absence of such a domestic source of supply was deplorable for several reasons, but there was always said to be "no money in it," and various ingenious theories were necessarily devised to explain the survival of the German firms, which certainly did not remain in business on philanthropic grounds alone. The shock of war galvanised this branch of industry along with many others, and it was widely declared that the gradually increasing supply of these materials should be augmented to the volume essential for the brisk practice of research, and should be maintained on a self-supporting basis even when free communication with Germany had become restored.

Encouraged by these patriotic pronouncements, the industry in this country has grown to respectable dimensions, and it does not seem fair, now that the famine in German products is over, to withdraw support from those manufacturers who have expended money and thought in meeting a national need at a critical period. That, nevertheless, is the logical outcome of present complaints. At the moment, it is possible to buy these materials much more cheaply in Germany, but that is due principally to the depreciated mark, and should not be allowed to weigh with those who have permanent national interests at heart. Moreover, comparison of current British and German prices is not the test which should be applied. It is more just and reasonable to compare current British prices with those of German materials prevailing in this country before the war. On this basis we have taken at random fifty typical substances and have found that in fifteen cases the present British quotations are lower. Furthermore, dividing the British (1922) by the German (1913) price, and averaging the factor for the fifty examples, an over-all factor of 1·4 ensues. Remembering that the corresponding factors given by the Ministry of Labour for April 1922 as compared with July 1914 are: Food 1·73, rent 1·55, clothing 2·40, fuel and light 2·15, other items 1·95, it will be seen that the foregoing factor, 1·4, is astonishingly moderate, bearing in mind the difficulties which attend the enterprise.

Another feature of the price question deserves appreciative recognition. While the Safeguarding of Industries Bill was under discussion, it was freely stated that the measure would lead to enhanced prices for the

domestic products involved. If, however, the quotations in April 1922 are compared with those in September 1921 for the same fifty typical materials it is found that, of the forty-six listed in the earlier catalogue, the price of twenty-four is unchanged, the price of twenty is reduced, whilst in two cases only has it been increased.

The question of quality obviously does not admit of discussion on a quantitative basis, but it will be recalled that even the long-established German firms were obliged to acknowledge sporadic blunders, and only the chemist who himself has never failed in preparing an organic material of the highest grade is entitled to withhold mercy, not to mention justice, from those manufacturers who have endeavoured to meet domestic requirements by covering a wide range as rapidly as possible. Surveyed generally, the British quality reaches a high standard.

Moreover, the range now offered is commendable. The organic chemist, particularly in the opening phases of an investigation, sometimes requires relatively obscure compounds in quantities of a few grams at a time, and the convenience of a British price-list comprising 2500 individual substances for use in research or analysis approaches, within a praiseworthy distance, the advantages offered by Kahlbaum and Schuchardt. There is no finality to such a list, which can receive additions when requirements are made known. Even the research chemist who has been mesmerised by the multitude and cheapness of German products, and by pre-war facilities for obtaining them must, on reflection, realise the burden which would be placed on a new industry by stocking every conceivable material, a large proportion of which would not be wanted for years to come. Finally, it should be represented that if the spell of German chemical superiority is ever to be broken, one factor in its dispersal is the demonstration, to successive relays of native students, that it is possible to produce in this country chemical materials of good quality and at reasonable prices. Moderate self-denial and exercise of fair-play during the next few years appear to be the principal equipment required in achieving this most desirable end.

M. O. F.

Northernmost Greenland.

Greenland by the Polar Sea: The Story of the Thule Expedition from Melville Bay to Cape Morris Jesup. By Knud Rasmussen. Translated from the Danish by A. and R. Kenney. Pp. xxiv + 327 + pls. and maps. (London: W. Heinemann, 1921.) 36*s*. net.

MR. KNUD RASMUSSEN occupies a unique place amongst polar explorers because, as the son of a Danish pastor in Greenland, he spent the first fourteen years of his life amongst the Eskimo, knowing their language like his own and entering into their modes of life as to the manner born. There was thus nothing strange or repulsive to him in the diet, the clothing, or the housing of the Eskimo, and after his education at the University of Copenhagen, he turned to the exploration of Greenland and the study of its people as naturally as a seal takes to the water.

In 1903–4 Mr. Rasmussen sojourned as a member of the Danish Literary Expedition among the "Arctic Highlanders," first discovered by Sir John Ross in 1818 and made familiar to English readers by Peary's repeated winterings. In 1910 Rasmussen established a station named Thule on the shore of Wolstenholme Sound, nearly in 77° N., and from this centre he made his "First Thule Expedition" in 1912–13; he crossed the inland-ice to the north-east, and proved that Peary was in error when he supposed that his Independence Bay was on a channel which cut off northernmost Greenland as an island. Rasmussen's intention had been to return to Thule along the west coast of Greenland from its most northerly point, but circumstances compelled him to go back by the way he came. An attempt to repeat the journey in 1914 failed, and the purpose of the book now under review is to describe the journey northward along the west coast which was carried out in 1917. The motive of the expedition was ethnographical—the discovery of the route by which the great Eskimo migration entered Greenland, and it was only preliminary to a greater journey, not yet completed, along the north coast of America.

The range of the journey is stated on the title-page as "from Melville Bay to Cape Morris Jesup," but was really less, as De Long Fjord was its termination. None of the ground traversed on the outward journey was new in the sense of first discovery, for the whole coast had been charted from the sea by expeditions which had forced their way through Smith Sound and the channels to the polar ocean, while sledge parties from Nares' expedition onwards had skirted much of the coast.

The interest of Rasmussen's journey lies in its methods as much as in its results. He was accompanied by two Scandinavian men of science—Dr. Koch, a Danish geologist, and Dr. Wulff, a Swedish botanist. There were also four Eskimos, and when the expedition started from Thule on April 6, 1917, it had 6 sledges and 185 dogs. The expedition carried a minimum of European stores and equipment so as to travel quickly, and beyond luxuries such as cocoa, tea, sugar, prepared oats, biscuits, and pemmican, all food was to be obtained by hunting.

The first day's journey was 94 kilometres, accomplished in ten hours, a magnificent performance on the sea-ice, which was never equalled afterwards; as

the distance is inadvertently given as "94 miles," the casual reader might suspect the author of romancing; but no explorer ever recorded his exploits more modestly. In many particulars it is a little difficult to follow the narrative, for the author is frequently obscure and discursive in his general statements, and the translator has been sorely troubled by the rendering of scientific terms. The reader may indeed feel a glow of justifiable satisfaction when he reasons out that the piece of apparatus designated a "cooking barometer" must be neither more nor less than a boiling-point thermometer! Also it takes time to accustom oneself to the one word "mountain," applied equally to mean mountain, hill, or knoll.

One has not to read far, however, before the narrative grips the attention, and the difficulties of style and terminology do not disguise the fact that Rasmussen travelled with the inherited skill and resourcefulness of the Eskimo and the insight of a man of science.

A series of helpful sketch-maps for each section of the journey is provided as well as an excellent general map. The route of the expedition ran north through Smith Sound, Kane Basin, Kennedy Channel, Hall Basin, and Robeson Channel on the sea-ice or the ice-foot, closely following the Greenland coast, stopping to hunt and gorge on seals, reindeer, musk-oxen, hares, or ptarmigan where game abounded, pushing forward desperately over the barren country, where the dogs had to be fed on their weakest comrades. At length on June 21, 1917, they reached the entrance to De Long Fjord in 83° N. and faced the problem of the return. The easy travelling of spring was past. It was impossible to move quickly over the thawing sea-ice; the sledges could not be dragged across the bare, stony coastlands with their sparse growth of the brilliant Arctic flora, and it was necessary to find a way up to the distant inland ice and to lay in a store of food for the long march over the empty snow-fields. A find of 24 tins, each containing 9 lb. of New Zealand mutton, left by the Nares expedition in 1875, before any of Rasmussen's party was born, had given occasion to much feasting on the way north, for the meat was as good after 42 years as if freshly tinned. One cannot help thinking that such a windfall of portable food might have been saved for the inland-ice journey; but the Eskimo rule of unlimited feeding when food is available appears to have been faithfully carried out.

It was the end of July before the party had got back to St. George's Fjord in 82° N. with all the fresh meat they could collect, and on August 4 they succeeded in ascending the glacier at the head of the fjord on to the inland-ice, with only 17 dogs remaining. Their supplies allowed only 12 days for making the journey to Cape Agassiz, south of the Humboldt Glacier. There they hoped to replenish their food supplies by hunting. One of the Eskimos had been lost in St. George's Fjord, they were all weak, and Wulff was very ill. It was 20 days before they reached the sea in a starving condition, all the dogs having been eaten. Rasmussen, with the strongest Eskimo, left the others and hurried southward along the coast, but by the time he met the native hunters and could send back supplies, Wulff had died. It is impossible to read of the hardships all had undergone without realising that the dangers of following Eskimo practice are very nearly equal to the advantages. It was October 22, 1917, when the survivors returned to Thule.

The scientific results of the expedition were substantial, and may to some extent be gathered from the narrative and the appendices. The map has been rectified in many particulars and the outlines of several fjords laid down for the first time. The extent of the ice-free land where life is possible has also been mapped in considerable detail. This lies between the sea-ice which never leaves the coast and the inland-ice which occupies the high land of the interior. The geology has been studied, and Koch is of opinion that the folded mountain system of the extreme north of Greenland is an extension of the Caledonian fold, which curves westward from Norway through Spitsbergen and continues westward of Greenland into Grinnell Land. Some interesting notes on air temperature are also given.

Dr. Wulff left valuable notes on the flora, including the observation that flowers formed one summer survived the cold of winter and matured in the second summer. The habits of the musk-ox are further elucidated and illustrated by excellent photographs, while there are many notes on insect life, the most curious being the appearance of enormous swarms of bluebottles, which make it almost impossible to keep meat killed in summer for more than a day or two in 82° N. The most important result, however, is the light thrown on the migrations of the Eskimo. Mr. Rasmussen has satisfied himself that they came from America, passed through Ellesmere Land, crossed Smith Sound, and moved down the west coast of Greenland, round Cape Farewell, and up the east coast. He is certain that they could not have reached the east coast by the shorter route along the north coast of Peary Land, which he thinks was never inhabited, and can never support human life.

The author refers in terms of generous appreciation to his predecessors of all nationalities, and amongst the most interesting illustrations are facsimiles of the letters deposited in cairns by parties of the Nares and Greely expeditions. The English version of the book

is appropriately prefaced by an appreciation of the author's work by Sir Lewis Beaumont, who himself did heroic service in leading one of the sledge parties from the *Discovery* nearly half a century ago.

HUGH ROBERT MILL.

Modern Tendencies in Physiology.

(1) *Practical Physiological Chemistry*. By Dr. J. A. Milroy and Prof. J. H. Milroy. Third edition. Pp. ix+449+ii pls. (Edinburgh: W. Green and Sons, Ltd., 1921.) 21*s*. net.

(2) *Biological Chemistry*. By Dr. H. E. Roaf. Pp. xvi+216. (London: Methuen and Co., Ltd., 1921.) 10*s*. 6*d*. net.

(3) *An Introduction to Biophysics*. By Dr. D. Burns. Pp. xiii+435. (London: J. and A. Churchill, 1921.) 21*s*. net.

THE curricula of most universities represent Natural Science as being made up of a number of subjects: geology, mineralogy, chemistry, physics, zoology, botany, human anatomy, and physiology, astronomy being grouped rather with mathematics than with natural science. Twenty years ago such a classification represented not only the scaffold on which the standard of departmental teaching and examination was erected, but it also represented the current conception of the limits between subject and subject. Where will these limits be twenty years hence? Everywhere the boundaries are disappearing; the physicist has made far-reaching additions to the basal conceptions of chemistry, the zoologist has largely forsaken animal morphology for fatherless frogs and the inheritance of sex characteristics. Of no department of science have the boundaries become less distinct than they have of physiology. One phase of the change which is taking place is emphasised by the publication of the three books, the titles of which stand at the head of the present article.

(1) "Practical Physiological Chemistry" written jointly by Prof. J. H. and Dr. J. A. Milroy, has already had a long and honourable career, and is now in its third edition. It represents the first phase in the change—that in which organic chemistry commenced to play a prominent part in physiology. In the present edition considerable additions have been made, especially in the direction of physical chemistry, but the book essentially stands for what it always did, namely, for physiology seen from the angle of the organic chemist, and as such its value is fully maintained.

(2) Dr. Roaf's book, "Biological Chemistry," represents a much more fundamental change. It deals with something wider than the mere chemical aspect of vertebrate physiology. As its title suggests, it embraces the chemical aspect of life generally, hence it includes not only invertebrate physiology, but botany in its bracket. The subject-matter of the book, therefore, covers parts of what formerly were regarded as three biological subjects, namely, physiology, zoology, and botany. It inevitably raises the question, "What are the real boundaries of physiology?" The question is a vital one in the teaching of science and medicine. Concrete instances of the transition which is taking place may be found in the organising of any medical school, and that of Cambridge may be cited as an example. Just before the war, the department of physiology was reorganised, a new laboratory was erected with much greater accommodation than the old one, yet at the same time experimental psychology and biochemistry were both recognised as new subjects and given laboratories of their own. In Manchester, where the subject of physiology has also been reorganised, the cleavage has taken place at a different point. Biochemistry remains a part of the subject, but histology has been handed over to the department of anatomy. What then remains as the essence of physiology? If it is to lose histology, experimental psychology, including a large part of the study of the organs of special sense, and biochemistry, what is to remain? What justification is there for a department of physiology at all?

In discussing this matter a couple of years ago, a well-known physiologist took up the position that what remained was biophysics. Turning then to Dr. Burns's volume (3), "An Introduction to Biophysics," it was a matter of peculiar interest to ascertain the extent to which it bore out the definition of being what remained of physiology after that subject had parted with biochemistry and experimental psychology.

Dr. Burns's book—incidentally we would remark that it is very nicely got up, being pleasant both to hold and to read—will well repay perusal, and should be read by both teachers and the more reflective class of students. The title of the book, however, seems to embrace less than the covers, but even granting that there is more in the book than is legitimately covered by the term biophysics, there still remains much of physiology which is not there.

The question then, what is left of physiology after biochemistry, biophysics, and experimental psychology have been taken from it, remains unanswered. The answer in our view is simply this—physiology remains. Biochemistry and biophysics are the apparatus of physiology, but they are not physiology. To the physiologist they are all-important, for to him every advance which is made in biochemistry is vital, because it gives him a new machine with which to explore his own department of knowledge.

To take a concrete example, nothing could be more truly in the domains of biochemistry and biophysics than are the chemical and physical properties of hæmoglobin. When our knowledge of these properties is complete—and it is now only commencing to open up—we shall be but in a position to commence the study of the red corpuscle—its birth, its fate, the extent to which it may be regarded as a living entity, and its relationship to other tissues in the body. These are physiology—physiology surely remains; and indeed these reflections apply not only to physiology but to pathology and medicine. It is only a matter of time till corresponding books on these subjects appear. There are chemical and physical aspects of pathology and medicine as truly as of physiology, but when pathological chemistry and the chemistry of medicine have said all that they should say, they too will be rather the necessary apparatus of pathology and medicine than the subjects themselves. Pathology and medicine will consist in the application of the chemical facts to the human subject as a whole—jointly with many other kinds of facts which are not chemical.

In the future of medical schools it would look as though chemistry and physics would be taught all along the line by persons specially qualified for the task, not merely as at present for the first M.B., or as in some cases organic chemistry for the second M.B. is now taught, not as side issues or luxuries or as the affairs of specialists, but as the necessary groundwork from which medical science grows—soil necessary to the tree. The line between the ground and the tree may be artificial and may be movable, but the distinction between the ground and the tree does not lack reality on that account.

Early Chinese Pottery.

The Early Ceramic Wares of China. By A. L. Hetherington. Pp. xviii + 160 + 44 plates. (London: Benn Bros., Ltd., 1922.) *3l. 3s.* net.

THIS excellent and trustworthy piece of work, obviously the fruit of prolonged research and consideration of the available evidence, is precisely the book one would recommend to the student or collector who was about to enter upon a serious study of the earlier Chinese pottery and porcelain with a view of forming a collection for his personal delight and study; for it is conceived and carried through in such a fine vein of reasoned enthusiasm that one could scarcely wish for a saner yet more inspiriting guide. Though our knowledge and understanding of the progressive steps by which the early pottery and porcelain of that vast territory were slowly brought to perfection are still incomplete, and must probably always remain so, really competent works such as this are of great value, if further progress is to be made in the task of elucidation, because they focus attention so clearly on what is known and, at the same time, remind us of the most important points that are still unknown or, at best, imperfectly understood.

European knowledge of the earlier centuries of Chinese ceramic history is a plant of slow and comparatively recent growth. There is all the more reason, therefore, to welcome a volume of this scope and style—illustrated by an abundance of choice examples which have been carefully selected from the most famous English collections, especially from those which are still in private keeping—which describes, in a connected narrative with copious references to the standard authorities, those delightful and alluring examples of the potter's skill which are anterior in date (many of them long anterior), to the foundation of that important masterful dynasty known as "The Ming" (the chiefs of a western warrior race which seized the Imperial throne in A.D. 1368, and held it in the most brilliant fashion for close on three hundred years).

Although the Chinese potters of Sung times, under their native rulers, had made an abundance of fine porcelains of superb artistic quality for some centuries before the advent of the Ming rulers and overlords, it was only during the sway of the latter that the mysterious substance, Chinese porcelain, found its way into the treasure-cabinets of European princes in any appreciable quantity. For centuries after its first sporadic appearance in Europe, the novelty of its substance, together with the matchless skill displayed in its fabrication and decoration, gave rise to a crop of the wildest legends and guesses as to its nature and composition. This is especially shown in the writings of our medieval European naturalists and alchemists, who, while groping in the dark among things old and new, were laying the foundations of modern scientific methods and knowledge. The era that saw the Ming emperors firmly seated on the throne of China was of great moment in the history of civilisation, for all over the old world a spirit of keen intellectual activity and enterprise worked like a new leaven, manifesting itself in eager inquiry into all the things of heaven and earth no less than in the accomplished production of fine material things. It seems like one of nature's own revenges that a period of time which was once a chosen domain for the historians of the drum and trumpet school is now seen to have been pregnant with discoveries and inventions which were to revolutionise the subsequent progress and prospects of mankind.

In a work of this class the reader will always consider

the sources to which an author attaches most weight, and here Mr. Hetherington proves himself at once catholic and discriminating. The older European authorities like Dr. Bushell, Sir A. Wollaston Franks, and his successors in the famous school of the British Museum have naturally been used to great advantage, while the writings of Mr. Berthold Laufer and other special workers in the history of early Chinese art have been drawn upon with discrimination. One would say off-hand that no modern opinion of value has been overlooked, while each, in turn, is supported or refuted from authoritative sources. This piece of patient toil has been carried out with much discrimination, as is especially manifest in the author's appraisement of the information that is to be obtained only from Chinese sources. The valuable original sources are set out in a select bibliography, where a list of the most important English and French works on the subject is also given.

The illustrations of the ancient wares, gathered from many sources, are worthy of the book and really illustrate it, while they have been chosen in a truly commendable way. Mr. Hetherington explains the manner of his choice in a few words which deserve to be quoted: "In selecting the illustrations I have followed a somewhat unusual course. The specimens chosen are not the rarest and most costly examples, nor are they taken from the great National Museums. I have illustrated typical pieces of good quality in the possession of private collectors. The ordinary person, in my opinion, wants to see the kind of thing he may hope to acquire for himself; not specimens worth a king's ransom which are never likely to adorn his cabinet."

WILLIAM BURTON.

Optical Theories.

(1) *Die Prinzipien der physikalischen Optik. Historisch und erkenntnispsychologisch entwickelt.* Von Ernst Mach. Pp. x+444. (Leipzig: J. A. Barth, 1921.) 48 marks.

(2) *Optical Theories: Based on Lectures delivered before the Calcutta University.* By Prof. D. N. Mallik. Second edition, revised. Pp. vii+202. (Cambridge: At the University Press, 1921.) 16*s*. net.

(1) ERNST MACH died in February 1917, at a time when civilised humanity was too busy to notice the passing of one who had made his influence felt wherever interest existed for the understanding of the fundamentals of mechanical and physical knowledge. The present work was published in 1921, but it is not a posthumous work, for it was ready before the war, and in fact the preface is dated July 1913. Although it went to press in 1916, the war and other causes delayed its issue.

As the title indicates, the book is an historical and epistemological account of the development of the principles of physical optics, the writer's aim being similar to that in his famous book on Mechanics. The book is thus not really a history, but rather a statement of the progress of ideas and of the manner in which they arose in the minds of their originators. Nobody who has read other books by Mach will need to be told that this volume is interesting and instructive: the description of the way in which the fundamental notions such as periodicity and asymmetry of the light ray emerged, is as fascinating as any romance.

The present volume was intended as a first part of a larger work: subjects like theories of the ether and relativity were reserved for the second volume. But the author's foreboding that this second volume would not be written by himself was unhappily justified.

Many points of interest emerge in the course of this history. Full tribute is paid to Newton's genius—it was Newton who first realised clearly the periodic nature of the light ray, later worked up into the wave theory, and its asymmetry, which became the theory of polarisation and the notion of the transverse light-vector. When Fresnel first reached the conclusion that light oscillations are transverse, the revolution in ideas was too great for even Arago, who refused to be associated with Fresnel's idea, and in fact, although Fresnel and Arago collaborated in many pieces of work, the transverse vibration theory was put forward in a paper bearing only Fresnel's name. Young's experiments did not at once receive the recognition they deserved, owing to the mistaken and reactionary servitude to all that was supposed to have emanated from Newton. The author has not much good to say about Schopenhauer's attempt at a theory of colours, while faint praise is all that is allotted to Goethe.

As already remarked, relativity as such is not discussed in this book, and even when Michelson's interferometer is described nothing is said about the 1887 experiment. Nevertheless the author felt it incumbent upon him to decline the honour of having been the herald (*Wegbereiter*) of relativity. On various grounds he refuses to accept the theory—presumably this refers to the restricted theory—and, while acknowledging the value of the relativist researches, he doubts whether the theory itself will find a lasting place in the physical *Weltbild* of the future. Mach asks: "Will the theory of relativity be more than an ingenious *aperçu* in the history of this science?" Would Mach's opinion have been affected by the events of 1919?

(2) The lectures delivered by Prof. Mallik at Calcutta in 1912 were published in book form in 1917, and the

book has been reissued in a second edition. It offers a brief technical *résumé* of the optical theories since Descartes and Fermat till the present day, a little being also said about ancient European and Indian ideas on the subject. The elastic solid theories, the electromagnetic theory, and the electron theory are passed in review, each treated briefly in mathematical manner, with its virtues and its imperfections exposed. In the second edition there are a few additions, notably on the theory of relativity in so far as it affects optics, and the opinion is expressed that this theory will not "dispose of the physical existence of the *etherial model*, until a better one can be found, which shall explain the intimate nature of the various concepts of modern physics, corpuscles and negative particles, electric charge and magnetic force, gross matter and gravitation, in one comprehensive scheme."

S. BRODETSKY.

Notes on Inorganic Chemistry.

Notes on Inorganic Chemistry for First Year University Students. By Prof. F. Francis. Pp. viii + 244. (Bristol: J. W. Arrowsmith, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1921.) 8*s.* 6*d.* net.

THE reputation which Prof. Francis has gained as a teacher is so firmly established that a book written by him on the lines that he has adopted for his lectures may be expected to be of much interest and value. Although the "Notes" have been written primarily for students of Bristol University they will, no doubt, be found useful by many others.

The book commences with a few interesting extracts of a philosophical nature from the works of various authors and a brief note on the indestructibility of matter; the subject of errors is then fully discussed, and the laws relating to gases are considered at length. The properties of hydrogen and oxygen are next described together with those methods of preparation which are of practical or theoretical importance. Opportunity is thus afforded for reference to catalysis, autoxidation, and the methods of determining the relative atomic weights of these two elements. The next three chapters are devoted to a discussion of the chemical atom, energy, thermochemistry, and to a fuller account of catalysis. In the chapters on the physical properties of water, a variety of subjects are discussed, such as vapour pressures and boiling points, the phase rule, solutions, osmotic pressure, electrolysis, dissociation, and the electron theory. The utilisation of atmospheric nitrogen in the preparation of ammonia and nitric acid is considered in some detail and the natural sources of these substances are mentioned. Reference to the action of sulphuretted hydrogen on arsenious acid serves as an introduction to a brief discussion of the chemistry of colloids, and in the remaining chapters Dulong and Petit's law, the periodic law, the laws of constant composition and of multiple proportions, the law of isomorphism, and the subject of valency are discussed.

The book is for the most part very clearly written, but typographical errors are rather numerous: for example (p. 9), $3{\cdot}1415^{10} = 93{,}621$, not $93{\cdot}621$; (p. 21) ρ' should read ρ; (p. 36) for Nitrogemn read Nitrogen; (p. 44) Lavoisier's name appears in place of Scheele's; (p. 56) for "proportional now" read "proportional. Now"; (p. 97) ·62%, etc., should be 62%, etc.; (p. 110) for Ladenberg read Ladenburg; (p. 179) for $HClO_4$ read $HClO_3$; (p. 205) the formulæ for apatite and vanadinite require correction; (p. 207) in the italicised sentence, "of" should read "or" and "methods" should read "molecule"; (p. 226) the constant m does not appear in the formula.

No doubt these mistakes will be corrected when a second edition is required.

There are a few statements which appear to be open to objection: On p. 23 Dalton's law of Partial Pressures is stated thus: "If P = total pressure and V = total volume,

$$P = p_1 + p_2 + p_3 \ldots;$$
$$V = v_1 + v_2 + v_3 \ldots\text{"}$$

It is not stated, however, that the second equality only holds if the volumes are all calculated at pressure P.

In the thermochemical equations on p. 57 it would perhaps be better to write $\frac{1}{2}H_2$ rather than H where molecular and not atomic hydrogen is meant.

On p. 65 there is the statement that "at 0° C. and 4 mm. pressure, Ice $\rightleftharpoons$ Water $\leftarrow$ Vapour." Presumably "$\rightleftharpoons$ Vapour" is intended, but, in any case, the triple point pressure of water is 4·6 mm., and at 0° C. and 4 mm. pressure water could only exist as vapour. A correct statement would be: "at 0·0075° and 4·6 mm. pressure

$$\text{Ice} \begin{array}{l} \rightleftharpoons \text{Water} \\ \quad\;\; \upharpoonleft\!\downharpoonright \\ \rightleftharpoons \text{Vapour.} \end{array}$$

It is stated on p. 88 that "one gm. molecular weight of Methyl Alcohol, 32·03 gms., dissolved in 1000 gm. of water raises the Boiling Point to 100°·52"; but, of course, all mixtures of methyl alcohol and water boil at a lower temperature than pure water. It is evidently assumed that methyl alcohol is practically non-volatile.

The following sentence occurs on p. 204: "atomic weight of Sulphur: atomic weight of Selenium = 18·39 : 45·34 of Sulphur = 32." Presumably the words "of Sulphur = 32" should be deleted. There is also a

discrepancy between the value 45·34 and that (45·40) given previously as the weight of selenium equivalent to 18·39 of sulphur.

Students who read this book carefully in conjunction with their lectures and laboratory work will be in a position to continue their studies in theoretical and practical chemistry with great advantage.

The Origins of Disease.

Organic Dependence and Disease: Their Origin and Significance. By Dr. J. M. Clarke. Pp. 113. (New Haven: Yale University Press; London: Oxford University Press, 1921.) 12*s*. 6*d*. net.

THE distinguished palæontologist who directs the New York State Museum at Albany has here brought together a number of instances of dependent life, tending to or attaining a parasitic habit, as presented by fossils mostly of palæozoic age. Some of these have long been known, others are due to Dr. Clarke's own skilled observation, but it is useful to have them all assembled. On this foundation is reared an edifice of philosophic conclusions, imposing in its dimensions and decorated with much verbal ornament. But, as in all great architecture, the main lines of the structure are few and simple, nor do they diverge unduly from accepted tradition. "Disease is any departure from normal living." "Normal living means full activity of an unimpaired physiology inclusive of the function of locomotion or mobility." Those who consider the lilies of the field will protest that these definitions are scarcely traditional. True; but, if they be accepted as interpretations of terminology, the actual theses will not appear so revolutionary.

The main conclusions are these. Among animals, at any rate, evolutionary progress has been always through those races that have retained full powers of locomotion. The assumption of a stationary mode of life is a step on the primrose path, and that one false step is ne'er retrieved. (Clearly Dr. Clarke does not believe in the fixed ancestor of the echinoderms.) The proportion of forms that retained their freedom was greater in the earliest known faunas. These statements are even more applicable to animals that have adopted a life of dependence on others. Simple association precedes either symbiosis or parasitism, and the evolution of a parasitic habit was gradual, extending it may be through many geological periods. This is well exemplified by the history of those simple sea-snails that took up their quarters near the vent of a certain species of crinoid and subsisted on the issuing stream—a history traced from Ordovician to Middle Carboniferous times. In treating of the oldest faunas, Dr. Clarke perhaps trusts too much to negative evidence, but his main lines of argument are reasonable enough.

It is of the host we speak as suffering from disease; but the parasite also lives a life that Dr. Clarke calls "abnormal" or even "unrighteous." Neither sin nor disease was "original" with life as a whole. Even the bacterium of the Precambrian was a free and independent organism. As for man, "it is safe to say that none of his physical ancestors have ever surrendered their physical independence or suffered essential modification through perturbation of their normal activities." Holding such views, Dr. Clarke naturally does not sympathise with some recent attempts to base evolution on pathology. He does not agree, for example, with Eccles that "The path of evolution is the path of past disease." He might, however, have discussed the further philosophical (or theological) question, whether sin and disease in a part of creation may not be a necessary condition for the evolution and salvation of the other part. Such lofty subjects may seem remote from the humble invertebrates of palæozoic seas, but Dr. Clarke is justified in his claim that a study of life-relations in their simple beginnings may furnish clues to our own social and psychic problems.

Shallow-water Foraminifera.

Department of Marine Biology of the Carnegie Institution of Washington. Vol. xvii.: *Shallow-water Foraminifera of the Tortugas Region.* By Joseph A. Cushman. (Publication 311.) Pp. 85+14 plates. (Washington: Carnegie Institution, 1922.)

IT is no disparagement of the excellent work which Dr. Cushman has already done to say that his report on the "Shallow-water Foraminifera of the Tortugas Region" marks a significant step in advance. We do not agree with his practice of reviving obsolete generic names, such as Discorbis, Quinqueloculina, and Triloculina; the first has long been abandoned in favour of Discorbina, and the two latter have become merged in Miliolina. It appears to be undesirable to complicate synonymies by the revival of early names. But, after all, this divergence of opinion is a minor point which, however confusing to the novice, in no way detracts from the value of Dr. Cushman's work to the advanced student.

The memoir is well worthy of its place amid the zoological literature published by the Carnegie Institution of Washington, and its value is increased by a map of the region, some excellent figures in the text, and fourteen plates which compare favourably with the illustrations of some of the author's earlier works, their enhanced value lying in the fact that they are original drawings "*ad nat.*," and not

mere *clichés*. The introduction contains valuable observations on living species, an addition to the scanty literature of this subject which has real interest. Dr. Cushman here directs attention to the protective coloration of a small crab which has reddish spots of the same colour as *Homotrema rubrum* (Lamarck), the remainder of its carapace and legs being of the same colour as the dead coral with which both the crab and Homotrema are associated. So far as we remember, this is the first record of a rhizopod in such a connection. There is also a short note on the colours of living Foraminifera, but this adds little to our knowledge of the subject, and we regret that Dr. Cushman, with the facilities at his disposal, has not gone more deeply into this question, especially as regards Homotrema, *Globigerina rubra*, and *Truncatulina rosea*.

Space does not permit us to discuss many interesting points raised by the author, but his observations are always temperate and demanding attention. We cannot, however, agree with his suggestion that *Marsipella cylindrica*, Brady, is really a species of Haliphysema. If we have any quarrel with Dr. Cushman it is but the old feud between "lumpers" and "splitters." Dr. Cushman has an enthusiasm for the creation of new species and varieties for what in many cases appear to be merely local variations, a practice which, in our opinion, is to be deprecated as tending to increase an already intolerable state of confusion. There is less excuse for him than for most "splitters," as his knowledge of the literature of the order is phenomenal. In this memoir, out of 144 species and varieties recorded 23 are described as new to science, and there are 9 others previously separated by the author. Consideration being had to the existing literature of West Indian Foraminifera, we cannot help regarding the proportions as excessive.

A. E.

Our Bookshelf.

Organic Chemistry, or Chemistry of the Carbon Compounds. By Victor von Richter. Edited by Prof. R. Anschütz and Dr. R. Meerwein. Translated from the eleventh German edition by Dr. E. E. Fournier D'Albe. Vol. 2: *Chemistry of the Carbocyclic Compounds.* Pp. xvi+760. (London: Kegan Paul, Trench, Trubner and Co., Ltd., 1922.) 35*s*. net.

"RICHTER" is too well known to need description, and the only matter requiring attention is the way in which the translator has done his work. In the first place, it must be pointed out that the German edition on which the translation is based was published so long as ten years ago, and the volume for review is, therefore, relatively out of date. In the second place, a much more serious fault is the surprisingly inexact way in which the translation has been carried through. Even an elementary knowledge of chemistry and of technical German would have prevented such translations as "carbohydrate" for "Kohlenwasserstoff," and would have allowed the German names "benzol," "anilin," "hydrazin," "hydrokinone," "mono-sulpho-per-acid," etc., to have been rendered into their English equivalents. As examples of chemical errors may be mentioned the use of *ferric* sulphate as a reducing agent, MnKO as the formula of potassium permanganate, etc. These are but a few of the elementary blunders for which the translator is responsible, and as a result the book will be found very confusing by students. As a book of reference for those who already have a good knowledge of organic chemistry it will certainly be found very useful.

The Chemistry of Combustion. By Dr. J. Newton Friend. Pp. viii+110. (London: Gurney and Jackson, 1922.) 4*s*. net.

THE account given by Dr. Friend of the chemistry of combustion, including flame, ignition temperatures, and the propagation of flame in gaseous mixtures, is clear and concise and should be of interest to students. Most of the newer work, especially that of Dixon and his students, is covered, and adequate references are usually given. If one might venture a criticism of many recent monographs, including that under review, it would be that far too little attention is now paid to the experimental methods. To young students a study of the way in which practical difficulties have been faced and overcome is of much greater value than a bald abstract of the results finally won. One misses here, for example, an adequate account of the highly ingenious apparatus of Dixon for the measurement of the velocities of detonation waves (is there not a difference between "detonation" and "explosion"?), and that of Petavel and of Pier for the measurement of explosion pressures (there is not even a reference to the latter). The collected numerical data in the book are useful; a more critical treatment would perhaps have been possible only if the author had been an expert.

A Course of Instruction in Quantitative Chemical Analysis for Beginning Students: With Explanatory Notes, Questions, and Analytical Problems. By Prof. G. McP. Smith. Revised edition. Pp. x+218. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1921.) 12*s*. net.

PROF. SMITH'S book is intended for students who have completed a year's work in elementary chemistry, including qualitative analysis, and are beginning the study of quantitative analysis. In England a certain amount of volumetric analysis is usually included in the first year's course at the university, so that some of the second half of this book could be used with intermediate students. The directions are usually arranged under the headings of "Method," in which a brief but fully adequate account of the process is given; "Procedure for the Determination," in which all the needful practical details of manipulation are described, so that the work of the demonstrator may be reduced to a minimum; and, finally, "Notes," in smaller type, which give the reasons for the procedure, equations, theoretical explanations (in which physical chemical conceptions are explained and used), and

practical hints. The book, which is attractive in appearance, is the work of an experienced teacher and can be recommended with confidence.

Experimental Physiology. By Sir E. Sharpey Schafer. Third edition. Pp. viii + 131. (London: Longmans, Green and Co., 1921.) 6*s.* net.

THIS laboratory manual of experimental physiology, first published in 1912, has now reached a third edition. To those who do not know the book it may be said that the matter is arranged in thirty-two chapters, each of which contains, on the average, enough to occupy the student for a laboratory period. The book does not deal with chemical physiology; hence the amount of time demanded by a course such as the present is more than some schools will find themselves able to devote to it; a certain number of the exercises, however, are intended for advanced students, though the author does not attempt to mark these off from the rest, the selection having been left to the teacher. The author's experience is a sufficient guarantee of the suitability of the matter, and of the method of arrangement; the descriptions of the experiments, though concise, are lucid; and the book is amply illustrated by ninety explanatory figures.

Laboratory Exercises in Applied Chemistry for Students in Technical Schools and Universities. By Dr. W. Moldenhauer. Authorised translation by Dr. L. Bradshaw. Pp. xii + 236. (London: Constable and Co., Ltd., 1921.) 12*s.* 6*d.*

THE long title of this book is somewhat misleading; "Technical Chemical Analysis" would have been much more appropriate. The explanations of industrial processes which are interspersed are clear and concise, but some of the methods differ from those in common use in this country. No mention is made of the important ammonia oxidation process in describing the fixation of nitrogen. The exercises cover a wide field, including water, fuels, alkali industry, fertilisers, metals and ores, oils, fats and waxes, soap, glycerin, and lubricants. The translation appears to have been carefully done, and the book may be recommended to senior students who intend to follow industrial chemistry.

The Haunts of Life: Being Six Lectures delivered at the Royal Institution, Christmas Holidays, 1920–1921. By Prof. J. Arthur Thomson. Pp. xvi + 272 + xvi plates. (London: Andrew Melrose, Ltd., 1921.) 9*s.* net.

THE Christmas Holiday Lectures at the Royal Institution have resulted in several books that charm the general reader as thoroughly as the spoken word held the attention of the juvenile audience to which the lectures were delivered. To those already existing Prof. Thomson has added "The Haunts of Life," where, in simple language, he sketches the problems that confront the inhabitants of the waters fresh and salt, shallow and deep, open and coast-bound, of the dry land, and of the air. His brief studies of animal adaptations, and of race-migrations from one "haunt" to another, are admirable, and open to the thoughtful reader a wide field of deep philosophic interest. The book should be on the prize-book list of every school.

The Alo Man: Stories from the Congo. By Mara L. Pratt-Chadwick and L. Lamprey. (Children of the World.) Pp. 170. (London and Sydney: George G. Harrap and Co., Ltd., 1921.) 3*s.* 6*d.* net.

THE series of which the volume under notice forms a part, is designed to open for young readers the study of geography and history as living subjects. It is written as a narrative of events in the tribal life of a boy and girl in the Congo Forest, culminating in an exciting fight between the tribe and a band of Arab slave traders which ends in the discomfiture of the latter. The Alo Man, a wandering story-teller, is responsible for the introduction into the narrative of a number of folk-tales of the animal type. The book is true to detail of a generalised forest type, although both type and area might perhaps have been more precisely defined with advantage.

Alternating Currents. By G. C. Lamb. Part I. Pp. viii + 73. 5*s.* 6*d.* net. Part II. Pp. viii + 127. 7*s.* 6*d.* net. (Cambridge: At the University Press, 1921.)

IN the books under notice a full explanatory syllabus is given of the lectures delivered to third-year students in the Engineering Laboratory at Cambridge. The volumes are meant primarily to be a help to the student when writing up his lectures. They will also be useful to teachers in technical schools, as the diagrams are beautifully clear, the descriptions are good, and many of the proofs given are very neat. The notation and nomenclature are practically international. "Effective," however, is now preferred to "virtual." Personally we prefer "sine-shaped" to "sinoidal," and "not sine-shaped" to "non-sine."

The Structure of the Atom: Notes on some Recent Theories. By Dr. Stephen Miall. Pp. iii + 26. (London: Benn Bros., Ltd., 1922.) 1*s.* 6*d.* net.

DR. MIALL states that he has published this pamphlet in the hope that it "might interest, and even instruct, some junior students of chemistry." To treat of the structure of the atom, radioactive changes, isotopes, and the octet theory in twenty-six pages, and in such a way as to be clear and interesting as well as accurate and instructive, is a task which calls for no little skill. Dr. Miall has undertaken it with a great measure of success, and his small pamphlet should fulfil the object he had in mind in its publication. If he had given some account of Sir J. J. Thomson's recent theory the whole range of the subject would have been covered: perhaps he will do this in future issues.

Insects and Human Welfare. By Prof. C. T. Brues. Pp. xii + 104. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1920.) 10*s.* 6*d.* net.

THOUGH embodying no original research, this book is a useful and pleasantly written compilation of the results achieved by economic entomologists (including medical investigators), and of the tasks that are yet to be undertaken in Man's battle with his most formidable rivals on earth. The majority of the statistics and facts narrated are from the United States; but this circumstance in no way impairs their value to the British reader, whether doctor, farmer, or forester.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Small Haloes of Ytterby.

The following letter, received from Mr. Svein Rosseland, of the Institute of Theoretical Physics, University of Copenhagen, contains an interesting suggestion. I publish it with the writer's consent.

"... In connection with your letter to Nature of April 22 on radioactive haloes in Ytterby mica I venture to comment upon the probable location of the hypothetical element in the periodic table. You make in your letter the interesting remark that the element cannot belong to the radioactive disintegration series previously known, since the life period, according to the Geiger-Nuttall relation, would have to be so immensely large, and the intensity of the radiation correspondingly feeble, that it is difficult to believe that the radioactivity of the element could be detected. This remark raises the question of the origin of the energy of the α-particles and the meaning of the above-mentioned relation.

Now it is known that the α-particles are strongly repelled by the nuclear electrostatic field of the parent atom, and it is clear that this repulsion must contribute appreciably to the energy of the particle. Without further knowledge of the exact dimensions of the nucleus and the character of the field close to it we cannot of course calculate the relative importance of this energy in the resulting energy of the particle, but we can calculate inversely a minimal radius for the nucleus of the transformation product by supposing the whole energy to be due to the nuclear electrostatic repulsion.

In this way we obtain a series of minimal radii for the elements consecutive to the α-radiating elements. The longer the life period the larger is this radius. The largest radius is afforded by uranium-X_1, where, corresponding to a range of 2·53 cm. N.P.T., it comes out as $6{\cdot}5\times 10^{-12}$ cm. This value is so large that in view of the experiments on single scattering it seems improbable that the real radius will be much greater. But then we are led to the assumption that the main part of the energy of the α-particle from uranium-1 comes from the nuclear repulsion. As it seems unlikely that variations in the nuclear dimensions will be so large as to account for the energy of the swifter α-particles, there must be an energy term of expulsion from the nucleus, resembling in some respects the energy difference between two stationary states of an atom. If we assume the term due to electrostatic repulsion to be only slightly variable, as is the case if the nuclear dimensions vary but slightly, the variability of the ranges of the α-particles will be due mainly to variations in this energy of expulsion, and it is this which is linked to the life period of the elements according to the Geiger-Nuttall relation. It seems not wholly improbable that the difference between the constants in this relation corresponding to the different series may ultimately be due to differences in the nuclear dimensions.

If the Ytterby haloes were due to an element of an atomic number of the order found in the families of the known radioactive elements, the nuclear dimensions of its transformation product would be nearly 1·8 as large as that calculated for uranium-X_1. If, on the other hand, we reject such a size for the nucleus as improbable, we can calculate the atomic number of the element in question by assuming a law for the large scale variation of the nuclear radii, assuming at the same time the energy of expulsion of the transformation to be small. As the volume of the protons included in the nucleus on the basis of current opinion is negligibly small, it seems natural to assume as a rough approximation that the volume of the nucleus is simply the sum of the volumes of the individual electrons contained in the nucleus, where, however, this electronic volume is not necessarily equal to that calculated from the mass of the electron. This assumption is equivalent to assuming the nuclear radii to be proportional to the third root of the number of electrons in the nucleus, $A-N$, where A is the atomic weight and N the atomic number.

Calculating in this way the radius of the transformation product of the element in question corresponding to a range of 1 cm. in air we finally arrive at an atomic number in the neighbourhood of 40. Since the β-radiating element rubidium is number 37 this calculation immediately suggests that hibernium is identical with yttrium, which is related to rubidium just in the right way to account for the β-radioactivity of the latter.

This calculation of course is to be regarded merely as a suggestion, but I should be interested to know if yttrium were ever found to be associated with Ytterby mica."

The conclusion arrived at by Mr. Rosseland seems not improbable. In a paper by Ivar Nordenskjöld (Bull. of the Geol. Inst. of Upsala, vol. ix.) two analyses of the black mica of Ytterby are given, one referring to a much altered variety and the other to a less altered mica. The former contains yttrium, the latter contains none. This suggests that the yttrium has been introduced in the process of alteration. The mica containing the reversed or bleached haloes has, to all appearance, been considerably altered. It is therefore probable that it contains yttrium. On the other hand, according to Mr. Rosseland's theory, rubidium should be present, or—derived from it by loss of a β-ray—strontium. Neither of these elements appears in the analyses. Nor am I aware of any mineral analysis in which there is an association of any two of the elements in question. But it is, of course, quite possible that spectroscopic examination of yttrium minerals would reveal such traces of rubidium and strontium as would support Mr. Rosseland's deductions.

Muscular Efficiency.

In Nature, April 15, 1920 (vol. 105, p. 197), there is a letter of mine on this subject, and the proposition there given relating to maximum efficiency is in the following applied to the case of the most efficient speed for a bicycle. The values chosen for the constants are merely guesswork, but the result is more or less in accordance with the facts.

The assumptions made are:

(1) The total power developed remains constant.

(2) All the power used in the acceleration of the limbs is lost.

(3) There is a perpetual leakage of power when a muscle is exerting any force.

I do not suppose that (1) is strictly true, but the tendency is in that direction.

I believe that (2) is correct, for no energy is restored when a contracted muscle is again extended either by the action of outside forces or by the contraction of other muscles.

(3) also is true, but in what way the leakage varies with muscular stress is not known. It probably lies between "as the force" and "as the square root of the force," and in this note I shall assume the latter hypothesis.

If P, P_A, P_L are respectively the total power developed and the powers lost by acceleration and leakage, then, f and v being the force and velocity, $P=fv$, $P_A=A/f^3$, and $P_L=Bf^{\frac{3}{2}}$.

The useful power is $P_E=P-P_A-P_L$, and the efficiency $E=1-\frac{P_A+P_L}{P}$. Differentiating E with respect to f it will be found that the minimum of P_A+P_L occurs when $f=\left(\frac{2A}{B}\right)^{\frac{2}{9}}$.

The constants A and B may be determined by the conditions that, when the whole power is expended in accelerating the limbs $A=f_a^3P$, where f_a is the force which can be maintained at the greatest practicable velocity, and $B=P/f_L^{\frac{3}{2}}$, where f_L is the greatest average force which the muscles can apply.

In the case of the bicycle I will assume (1) that the gearing is 70 with a 7-inch crank; (2) that the power available is 40 ft. lb. per sec. (about 1/14 H.P.); (3) that the greatest speed attainable with that power and in the absence of air resistance is 40 ft. per sec. (about 28 M.P.H.); and (4) that the greatest average force which can be continuously exerted on the crank is 30 lbs., from which it may be deduced that A = 5000 and B = ·24.

These values were used in computing the curves in Fig. 1.

The minimum of P_A+P_L is 12·5 ft. lbs. per sec., thus leaving 27·5 ft. lbs./sec. for useful work, which, with the assumed length of crank and gearing, would

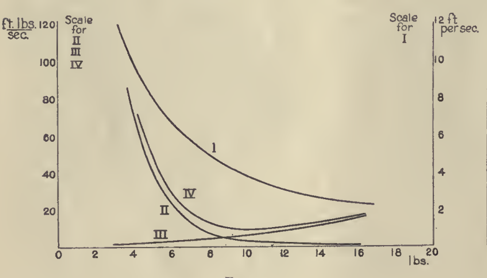

FIG. 1.

Curve I is the hyperbola $fv=P$; f in lbs., v in ft. per sec.
,, II P_A, the power lost in acceleration of the limbs.
,, III P_L, the power lost by leakage from the strained muscle.
,, IV P_A+P_L, which has a minimum value of 12·5 ft. lbs./sec.

suffice to lift a load of 200 lbs. (weight of rider and machine) up a gradient rather less than one in thirty. Hence even with this gentle gradient it would pay to ascend the hill obliquely, *i.e.* in a series of tacks.

The P_A+P_L curve, however, is very flat near the minimum, so that a considerable increase of gradient would not do much to diminish the efficiency.

Whether the assumed maxima of speed and force are anywhere near the truth I do not know, and it would be interesting to have laboratory experiments on these quantities.

"G. B. M."

I FIRST saw the late G. B. Mathews on June 4, 1884, at the Queen's Hotel, Chester, when the staff of the newly founded University College of North Wales was appointed. He was chosen for the Chair of Mathematics, and almost from that time we were linked together in friendship as well as in our offices as teachers of intimately related subjects in the same institution. I well remember his youthful and striking yet attractive appearance. He was the senior wrangler of the previous year, and came full of eager enthusiasm for the teaching of mathematics and for original mathematical work, and for ten years laboured hard in the hope of founding something like a school of mathematical study in North Wales. But alas! these hopes were dashed. Perhaps he was a little impatient, and I certainly did my best to counsel him to wait, and to find out the effect of the new Welsh university on the studies of the place, but without effect. The best of the Welsh students were at that time attracted by the Neo-Hegelian philosophy, and some of them, as seems to be the way of such students, seemed not a little proud that their mental tendencies were not mathematical. To this curious type of intellectual pride Mathews referred eloquently in the posthumous paper published in NATURE of April 22.

In that paper he lamented the revival of the fallacious arguments for the supremacy of the Latin-Greek classics as an educational instrument; but he in no way undervalued classical culture, only he thought that to an Englishman, the inheritor of a copious and flexible language, and of a literature unequalled in the past, a training in Latin and Greek was far from indispensable, and might have its disadvantages. Certainly many classical people, tutors of colleges and old-fashioned classical schoolmasters, often write English which can scarcely be regarded as a model to be imitated, as any one can convince himself by reading the prefaces and introductions to editions of classical texts. He always thought Greek more important for students of science than Latin. And truly the technical language of zoology and physiology, and in a less degree that of physics, is much more exclusively of Greek than of Latin derivation.

Mathews had a knowledge of Latin and Greek as minute and accurate as that generally possessed by professional classical scholars. He wrote pure and elegant Latin. I remember his amusing himself by turning into Latin prose an original philosophical dissertation which happened to come into his hands and arrested his attention. I remember also some Latin verses which he published anonymously and which were much praised by a very eminent scholar.

He wrote also charming English essays in the style of Charles Lamb, of whom he was a great admirer. These I fear are lost, but one of them, "On a cock-loft," was a perfect gem, a charming piece of the most natural and simple prose, somewhat after the manner exemplified more recently by Kenneth Grahame in his "Golden Days." He gave much time to Arabic in later years, and it is to be hoped that his translations of Arabic poetry will ultimately be published. I have seen some of them, which certainly seemed very remarkable. His most valuable work was done in mathematics, and this has been well appraised by a mathematician who knew him well in later years. It is, I think, a pity that the variety and strength of his interests distracted him from mathematical work, and prevented him, until it was too late to take it up again, from finishing his work on the Theory of Numbers. But in his NATURE articles his extraordinary wealth of knowledge and his keen and yet genial criticism must have helped innumerable students. A. GRAY.

The University, Glasgow.

Half Quanta.

THE Wilson-Sommerfeld principle when applied to the case of a rotating molecule, supposed rigid, leads to the expression $mh/2\pi$ (m integral, h Planck's constant) for the angular momentum of the molecule, and on this basis, with the help of several other assumptions, it has been found possible to account very satisfactorily for the main features of the structure of band-series. The theory is found to apply not only to ordinary bands in the region of the visible spectrum but also to absorption bands of very different appearance, such as those due to the halogen acids which occur in the infra-red. In the latter case, however, a discrepancy exists which has given rise to a good deal of discussion. The observed bands consist of a number of lines distributed, to a first approximation, according to the formula

$$\nu = \nu_0 \pm m\omega,$$

where m takes successive positive integral values and ω is a constant. The line of wave-number ν_0 (*i.e.* $m=0$) is invariably absent.

The theoretical expression, on the other hand, is of the form

$$\nu = \nu_0 \pm (m - 1/2)\omega,$$

which, it will be noted, represents a similar set of lines displaced through a distance $\omega/2$. The reality of the discrepancy is therefore dependent upon the correct identification of ν_0, and as this is not entirely beyond question some workers have preferred to take the value indicated by the theory, although by doing so fresh difficulties in the interpretation of the results arise. Einstein, however, pointed out (quoted by Reiche, *Zeitschr. f. Phys.*, 1920, p. 283) that theory and observation would agree if instead of the usual value $mh/2\pi$ for the angular momentum one assumed it to be given by $(m+1/2)h/2\pi$. The evidence from the infra-red absorption bands seems scarcely strong enough to warrant such a revolutionary change, but other data bearing on the question have recently become available. In the band spectrum of helium, for example, series exist which show this same peculiarity, and here its existence is indubitable, for the normal (*i.e.* theoretical) series are in this case also present, and a trustworthy value for ν_0 can be determined from them.

Following up Einstein's suggestion, I have found that the abnormal series may in all cases be very simply derived from the normal group by displacing the quantum number by one-half. As an illustration of the sort of agreement which is obtained I may cite the case of the $\lambda 5730$ band (see Curtis, Roy. Soc. Proc., 101, 1922, p. 38), which consists of six series, only three of which satisfy completely the theoretical requirements. The "half-quantum series" calculated from these three are as follows:—

$$17436{\cdot}6 - 31{\cdot}5m + 0{\cdot}95m^2$$
$$17436{\cdot}6 + 31{\cdot}5m + 0{\cdot}95m^2$$
$$17436{\cdot}6 + 0{\cdot}95m + 0{\cdot}95m^2$$

The remaining three observed series are represented by the formulæ:—.

$$17437{\cdot}3 - 30{\cdot}0m + 0{\cdot}87m^2$$
$$17436{\cdot}8 + 29{\cdot}5m + 1{\cdot}09m^2$$
$$17437{\cdot}3 + 1{\cdot}15m + 0{\cdot}87m^2$$

The correspondence is very close, having regard to the approximate character of the formulæ upon which the calculation is based. It is certainly good enough to justify the proceeding as an empirical method of expressing the relationship between the two groups and to encourage theoretical inquiry into its physical significance.

As the matter stands at present, the inference—illusory though it may be—is that the molecules fall into two classes, according to whether their angular momenta are given by $mh/2\pi$ or by $(m+1/2)h/2\pi$. Transitions between the two classes do not occur (or, if they do, give rise to no radiation), since there are no lines corresponding to changes of one-half in the quantum number. That is to say, whether or no the half-quantum may be involved in the determination of the possible states of a molecule, it does not appear to play any direct part in the radiation process.

Fossils in Burmese Amber.

AMBER mines have long been known in Upper Burma, or rather in the adjacent "unadministered tracts." In 1916 Mr. R. C. J. Swinhoe, of Mandalay, began to send me specimens of Burmese amber (Burmite) containing insects. As opportunity has offered, he has continued to obtain such material, all of which has been transmitted, after investigation, to the British Museum (Natural History). Up to the present time I have been able to describe 38 species of insects, three arachnids and one diplopod. Many other species, which I did not feel competent to deal with, or which could not be seen properly, exist in the amber, and will, I hope, eventually be described by others. On the whole, the fauna is very remarkable, containing a large preponderance of types which are usually considered primitive. The amber was said to come from Miocene clay, in which, however, it was presumably of secondary origin. Judging from the fossils, I suggested as early as 1917 that the amber might be actually very much older than Miocene, conceivably even Upper Cretaceous (*Amer. Journ. Sci.*, Nov. 1917, p. 360).

Recently, information has been received which tends to confirm the suspicion that the amber is much older than Miocene. Dr. F. A. Bather of the British Museum has kindly transmitted a letter from Dr. E. H. Pascoe, Director of the Geological Survey of India, dated July 20, 1921. Dr. Pascoe states that Dr. M. Stuart, in his recent journey down the Hukong Valley, saw something of the amber mines, and reported that the shafts were sunk in beds which appeared to be identical with the Tipam sandstone or the Irrawaddy series. Whether they passed through into underlying rocks could not be determined, but from the evidence obtained by Noetling and others it seemed probable that they frequently did. The Tipam sandstone is unconformable on the underlying beds, and frequently contains fragments of them in its lowest horizons. Such fragments may very well include lumps of amber derived from the underlying clays. Dr. Pascoe continues: "Among the debris of some pits sunk into these clays, which are the true home of the amber, Dr. Stuart found a fragment of chalky nummulitic limestone. The pits had been sunk into the clays, not to obtain amber, but flint from the chalky limestone lying in them. Dr. Stuart describes the clays as totally unlike any Disang beds that he had seen, and he is inclined to accept the view that they are Eocene in age. If it is possible to determine the species of the nummulite, I will let you know; but it is, of course, not certain that this nummulitic limestone occurs *in situ* within the clays."

On August 1, 1921, Dr. Pascoe wrote that Dr. Stuart thinks the nummulite is *Nummulites biaritzensis* d'Arch., characteristic of the uppermost zone of the Lower Khirthar. The Khirthars correspond approximately, according to Mr. E. Vredenburg, to the Lutetian. The Lutetian represents the earlier part of the Middle Eocene, below the Bartonian.

Thus, the evidence seems to indicate that the Burmese amber fauna is Eocene, and older than the Eocene (Bartonian) beds which have produced fossil insects in the south of England.

At this point, however, a new problem is introduced. A few days ago I received from Mr. Swinhoe a number of beads of extremely pale and pellucid amber containing well-preserved insects, all different from those previously described. These insects include a small bee, which seems not to differ at all from the common living Indian *Trigona lævicep*s Smith. The other amber contained no ants, but this includes a worker of Crematogaster, workers of Pheidole, and males of Monomorium. I also find a winged termite, a psyllid, a fly of the genus Phlebotomus, some acalyptrate muscoid flies, a mycetophilid, some small spiders, etc. So far as can be seen, this is a modern series of types. Mr. Swinhoe found that the beads, when he purchased them, had been artificially coloured to enhance their value, and he had this colouring matter removed. He learned that several stained necklaces had been imported from China, so he could not be sure that the material was really from Burma. At one time he even wondered whether the specimens could have been included in artificial amber, as is sometimes done. He decided that this last suspicion was unfounded, and I quite agree. His letter ends: "Probably this light amber comes from a locality a few miles off." My own opinion is that this light amber (or copal) is of very recent origin, not earlier than Pleistocene, and contains a fauna which doubtless consists mainly (at least) of species still living. The bee which I recently described as *Meliponorytes* (?) *devictus* probably belongs to this material, and not to the Eocene amber. We may surmise that we have the product of some Dipterocarpaceous tree allied to Vateria; something similar to Miss Ruth Holden's *Dipterocarpoxylon burmense*, based on fossil wood from Burma. More exact information on this matter is greatly to be desired.

T. D. A. COCKERELL.

University of Colorado, May 1, 1922.

Radium Synthesis of Carbon Compounds from Air.

Now that photo-synthesis is attracting special attention it may be interesting to record some recent preliminary experiments on the production of synthetic carbon compounds by the action of radium rays on atmospheric air. Under normal conditions of temperature and pressure, it seems evident that this radio-synthesis is capable of producing carbon compounds apart from living cells, and without the agency of solar radiation.

The experiments arose from an observation, made some nine years ago, during an investigation of the curvature of thin plates of mica when acted upon by radium. After long exposures—some weeks in duration—I noticed a deposit of brown patches, mere specks, on the uppermost side of the thin strips, that is, the side which became concave during α-ray bombardment.

As this deposit was found not to be responsible for the bending, it was not mentioned in the resulting paper (Journal Röngten Society, No. 44, vol. xi., "Alpha Ray Effect Mechanical"), but left for future investigation, which eventually had to be abandoned on account of urgent war work.

Having recently made further experiments, I find that the deposits can be detected more quickly, and better observed, by using freshly drawn fibres of quartz or glass, diameter about 0·04 millimetres. Several of these may be spaced about 1 mm. apart, supported on a framework immediately over the radium salt, about one-eighth of an inch above the uncovered radio-active surface (one or two milligrammes of radium or mesothorium is sufficient).

The whole arrangement should be put into a clean cardboard box (about one litre capacity, to reduce convection currents), with loose fitting lid, which is then put away in a dark room. After remaining undisturbed for a week, it will be seen, using a Coddington lens (or better if transferred to a microscope with one-inch objective), that the fibres are covered with a clear white viscid liquid film, which is beginning to gather up into beads, or droplets, at more or less regular distances. After a further exposure of a few days, it will be found that all the droplets have increased in size, some having reached a pale sherry colour. Further exposure leads to increase in size, eventually resulting in dimensions about double the diameter of the fibre. The colour changes may be from white to sherry, red, then dark brown, after about six weeks' exposure; later a little irregularity of contour of the brown droplets may be noticed, showing that the liquid is tending to solidify with irregular contraction; fresh deposits may appear in the interspace between old droplets, so that a fibre may contain droplets in all stages.

It is evident that the first liquid product, colourless at the beginning, is soon oxidised in the ozone which is produced by the α-rays. By reason of the time required and the minute quantity of the first product, it is difficult to make tests before oxidation has taken place to some extent.

Preliminary microscopical examination of the final dark brown product, which becomes a strongly adherent scaly deposit, on a mica strip (after nine years), demonstrated that the brown deposit was insoluble in alcohol and chloroform but dissolved in hot water. On evaporation of this solution a brown film was formed which cracked into scales on drying. This film became carbonised on heating, at about the same temperature as a particle of gum acacia, on the same electric hot-plate.

So far, I have not obtained deposits by using α- β- or γ-rays, either separately or in combination. The gaseous emanation of radium seems to be necessary, which points to the probability that the radium products of short period are chiefly concerned in the synthesis, or in facilitating condensation on solids. On this point, and on the physical aspects, further experiments are in progress, but it is very desirable that the chemical examination of the products should be made by others with better facilities than those I possess for dealing with very minute quantities. Possibly increased production may be obtained by increasing the proportion of water vapour and carbon dioxide in the air. I should be very glad to know of any work already done bearing on the subject. Have such products ever been found in the atmosphere? If ultra microscopical, rain may contain some.

F. HARRISON GLEW.

156 Clapham Road, London, S.W.9.

Cephalic Index and Sex.

IN NATURE of March 23, p. 389, I find the statement—in a summary of a paper by Miss R. M. Fleming—that "British women show more development of pigment, brachycephaly, and prognathism than do men."

As to the cephalic index I see quite the same in Arthur Thomson and Randall-MacIver's interesting account of skulls from "The Ancient Races of the Thebaid" (Oxford, 1905); and probably this "more development of brachycephaly" in women is a general law.

But, as I pointed out in 1907, in my Danish paper, "Om Kortskaller og Langskaller" (Oversigt over D. K. Danske Videnskabernes Selskabs Forhandlinger, 1907)—also published in a German translation in "Archiv für Rassen- und Gesellschafts biologie" (IV., 1907)—such indications need correction because of the correlation between absolute length of skull and cephalic index: the index diminishing greatly with increasing length.

I will here reproduce only one of the concluding tables of my paper in which I have given computations of the English authors' splendid material. The whole of the material (775 males and 754 females) gives for the skulls these averages:

Males: L., 18·426 Br., 13·536 Index, 73·48
Females: L., 17·682 Br., 13·187 Index, 74·58

i.e. showing "more development of brachycephaly" in women.

But if we compare what ought to be compared, namely, the skulls having the same lengths, we find quite different results.

Comparisons of the cephalic index in men and women within the same classes of absolute length are given in the following table:

Limits of Length-Classes.	Index of Skulls.		Difference and Mean Error.
	Male.	Female.	
17 cm. – 17·5 cm.	77·34	75·86	1·48±0·47
17·5 ,, – 18 ,,	75·40	74·28	1·12±0·29
18 ,, – 18·5 ,,	73·88	73·18	0·70±0·30
18·5 ,, – 19 ,,	72·42	71·24	1·18±0·51

The same divergence runs through all special series of the material. The same class of absolute length of head (again correlated with the height of body and so on) shows more development of brachycephaly in *men* than in women!

In this short letter I need not enter into the various questions concerning cephalic index and heredity, Mendelism, etc. W. JOHANNSEN.

University of Copenhagen.

THE point which Prof. Johannsen raises is interesting, though absolute measurements on men and women are scarcely comparable. Absolute measurements on women are not only smaller than those on men of the same type, but also differ in their relationships. As pointed out in a summary of our measurement results in *Man* for May 1922, a range of absolute head length 181-193 mm. in women of a certain race type corresponds with a range of absolute head length 194-204 mm. in men of that race type. It will thus be seen at once that a comparison of a man and a woman having the same absolute head length means a comparison between two people not only of different sex, but also of different race type. In such a comparison one gets a woman towards the long headed end of the series compared with a man towards the short headed end of the series for that sex. The smallest absolute measurements for head breadth are among women, for all women's measurements are small, but at the same time these heads need not necessarily be narrow proportionately to their length, which may also be very small. Classifying race types on the basis of summation of characters our thousands of measurements undoubtedly show that women's heads show greater *relative* breadth (*i.e.* are not so oval in shape) as those of the men nearest to them in general features.

In conclusion, may I refer to Prof. Johannsen's mention of length of head *correlated with height of body*. Our results have gone to show that on the whole the greatest absolute length of head is to be found in a race type the height of which is distinctly sub-normal. The longest headed man I have measured is of this type and is under five feet in height. This of course may not apply to the race types Prof. Johannsen has measured, but it would be interesting to have his observations on the point.

R. M. FLEMING.

The Organisation of Knowledge.

REGARDING the remarks made in NATURE of May 6 on the address of Dr. F. L. Hoffman at the American Association, it might be suggested that the organisation of facts for commercial uses is of a different order than the organisation of knowledge for the purpose of understanding the operations of Nature or of ascertaining a particular law of cause and effect. A man who collects data may, or may not, have imagination. A man may also classify facts quite mechanically according to a scheme laid down. The successful "business organiser," however, usually has a new plan and sets others to work to collect facts for him to organise or re-organise. He knows at the start *why* he wants the facts and *how* to use them. Imagination is required by such an organiser because he has to adjust his methods not only to his data but to human beings and a changing world.

Mathematics, however, in the Pythagorean sense of *Mathesis*, certainly is not necessary for the actuaries' arithmetical operations. But, so far, neither actuaries nor the inductive method of inquiry alone have been able to predict epidemics of disease, revolutions or wars, not to mention earthquakes and tidal waves; nor have they anticipated discoveries of fundamental laws, such, for example, as that of Dalton's doctrine of atomic proportions or Faraday's law of electromagnetic induction. Dalton, we know, was a mathematician and was not personally engaged in collecting evidence; his laboratory work was insignificant. Faraday himself stated that he had reached his conclusion by a *process of thought* and *knew* it must be true before he obtained the evidence by experiment. Who, even then, suspected the industrial results that followed in later years through the application of the principle by others? It is to mathematics in the original Greek sense of principles or proportions (not *calculation* merely) that we owe the really epoch-making discoveries of science. Even inventions are not the result of examining facts. A mechanical genius has a knowledge (instinctive or mathematical) of a law he tries to demonstrate practically; he does not attempt to formulate a law from a collection of facts. The evidence proves the law to the senses; but a law is not created nor even discovered by evidence. Inductive science has been necessary in order that we should become acquainted with the different kinds of materials and variety of species, etc., in the world, for, before Bacon's instructions had been carried out, there was no opportunity to apply the laws of Nature (understood, without doubt, in a general way by Bacon himself) even when a genius with mathematical imagination saw them in his thought. Inductive and deductive methods are each ineffective without the other.

Again, the history of modern chemistry and physics does not support the contention that the laws of mechanical engineering were evolved by rule-of-thumb experiments amongst primitive peoples before, for instance, the pyramids could be built. Modern hydraulic engineering arose in the mind of one Carnot, a mathematical genius who demonstrated its laws

by symbols on paper. Industry and business have benefited considerably from the application of this *unbusinesslike* mathematical method !

The fact is that the most practical sciences, and the only sciences that have been applied industrially, are the exact sciences of chemistry, physics, and engineering—sciences which can predict effects from known causes.

No statement of evidence is really a fact until all the factors are known, and, therefore, statistics cannot predict, and man cannot forestall disease or economic distress, in spite of the sciences of biology and medicine and the "science of economics."

W. WILSON LEISENRING.

IN a notice (NATURE, May 6, p. 596) of an address by Dr. Hoffman, the words are used: "Imagination is what the mathematician is ever trying to get rid of." As such misconceptions as this are unfortunately rather widespread, it may be useful to protest against them. Imagination is essential to mathematics. The work of the great mathematicians affords many striking examples of creative imagination, and for the proper understanding and appreciation of even the elementary parts of the subject the use of imagination is necessary. One of the most important qualities of a good mathematical teacher is the power of stimulating the pupils' imagination, and it is, perhaps, the neglect of this faculty by some teachers which is responsible for the dulness and lifelessness of what is too often taught in schools under the name of mathematics. F. E. CAVE.

Girton College, Cambridge, May 10.

DR. HOFFMAN'S charge against the mathematicians was not that they lack imagination but that they set before them as the ideal of their science the getting rid of it. The quotation from Prof. Whitehead, who certainly is not lacking in that faculty, makes the meaning clear. There is, however, a drawback in our language in the fact that we use the same word for imagination when we mean æsthetic creation, what the Italians call *fantasia*, as we do when we mean the anticipation which is pure reproduction, what the Italians call *immaginazione*. It is of course the æsthetic creation the mathematician aims at dispensing with in order to preserve the purely logical character of his ideas. Even Kant represented it as a kind of handicap that mathematical concepts should require sensuous intuition for their expression. THE WRITER OF THE ARTICLE.

The Elliptic Logarithmic Spiral—a New Curve.

IF, in an elastic system with one degree of freedom, and friction proportional to the velocity, the relation of the "free" force to the displacement be considered, an interesting curve results.

Thus if the displacement be

$$x = ae^{-kt} \cos nt$$

the force is given by

$$F = be^{-kt} \cos (nt + \epsilon),$$

and by eliminating the cosines we have

$$\frac{x^2}{a^2} - \frac{2Fx}{ab} \cos \epsilon + \frac{F^2}{b^2} = e^{-2kt} \sin^2 \epsilon,$$

which may be termed an elliptic logarithmic spiral or a damped Lissajous' curve.

If the vibrations are maintained or forced by a force of harmonic character, the force displacement curves become ellipses.

The same equations hold for the compounding of two damped harmonic motions of equal periods at right angles, so that the path of a body at the lower part of an oiled sphere or of the bob of a conical pendulum in a viscous medium would be, in plan, an elliptic logarithmic spiral. H. S. ROWELL,
Director of Research.

Research Association of British Motor
and Allied Manufacturers,

Intelligence Statistics.

I WAS interested in a short note in NATURE of February 16, p. 218, on the dependence of the standard of intelligence of individuals on the part of the year in which they were born. Statistics appear to show that the standard of intelligence is higher in individuals born in the autumn (say October) than in those born in the spring (say April). At first sight this result may seem rather unexpected, as one might expect that the influence of summer would be beneficial to a child born in the spring, whereas, in the case of a child born in the autumn, it would not be surprising if the succeeding winter were to have a deleterious effect on the mental growth.

It appears to me that the chances of a child surviving the first year of life are greater for a child born in the spring than for one born in the autumn, and I do not doubt but that statistics have shown that this is so. Coupled with this one would expect that the general "fitness" of the survivors of the first year of life would be greater for individuals born in the autumn, because the weaklier members have been weeded out by the severity of winter in the first few months of life. This would appear to be sufficient to explain the result mentioned at the beginning of this letter. We should thus expect that, in the southern hemisphere, children born in the spring (April) would in later life have a higher average standard of intelligence than those born in the later months of the year. Statistics from the southern hemisphere would thus be of value in this connection.

It is possible that this aspect of the problem has already been dealt with. As the papers on this work are not accessible to me, however, I have not seen the explanations offered for the above-mentioned interesting phenomenon. ROBERT W. LAWSON.

The University, Sheffield.

A Rainbow Peculiarity.

IN NATURE of March 9, p. 309, Major Lockyer asks if it is a fact of general observation that "the whole area of the inside of the primary bow is brighter than the region outside," and he refers to the phenomenon as "a fact in Nature which appears to have been rarely noticed visually." The following quotation from "The Divine Adventure," by Fiona Macleod (William Sharp), shows that the mystic poet not only saw clearly into the heart of Nature, but was also a keen observer of her outward manifestations:

> It is not Love that gives the clearest sight:
> For out of bitter tears, and tears unshed,
> Riseth the Rainbow of Sorrow overhead,
> And 'neath the Rainbow is the clearest light.

Probably the phenomenon was commonly known amongst the Western Isles he loved so well.

JOHN P. DALTON.

Non-Specific Therapy.

By Dr. J. STEPHENSON.

IN inoculation against typhoid fever, dead typhoid bacilli are injected subcutaneously or into a muscle. Inoculation against plague consists in the injection of an emulsion of dead plague bacilli artificially grown in broth. These are prophylactic measures for the protection of persons who are likely to be exposed to infection. Hydrophobia vaccine, used in order to prevent the development of the disease in persons who have been bitten by a rabid animal, is prepared according to a definite system from the spinal cords of rabbits inoculated with the disease. Antidiphtheritic serum, used in the treatment of patients actually suffering from diphtheria, is the blood-serum of a horse which has had diphtheria toxin (the broth in which diphtheria bacilli have been grown, and from which the bacilli have been filtered off) repeatedly injected into it.

In using vaccines the object is to stimulate the individual to produce protective substances in his own body; in using sera, the protective substances, elaborated by some other animal, are themselves supplied to the patient. But in all the above instances, and in numerous other similar modes of treatment,—whether the treatment takes place before infection (*i.e.* is prophylactic), or is carried out during the incubation period, or during the actual disease; whether bacilli are used, or a serum free from bacilli but containing an antitoxin,—the implication is that certain substances are protective against one disease, certain other substances against another; in other words, the treatment is *specific*. The idea of specificity may go even further, as where a patient is treated by means of the particular strain of micro-organism, or the particular mixture of them, that he himself harbours (the use of autogenous vaccines in asthma, acne, boils, etc.). As Sir Almroth Wright has recently written:—

"That immunisation is always strictly specific counts as an article of faith; and it passes as axiomatic that microbic infections can be warded off only by working with homologous vaccines, and that we must in every case, before employing a vaccine therapeutically, make sure that the patient is harbouring the corresponding microbes."

To attempt treatment on a non-specific basis would seem therefore at first glance to be a step backward, and investigation of such a subject illogical, if nothing worse. But while reason, working on the accepted lines, was all against the idea, facts have cropped up repeatedly which seem to give a value to non-specific treatment. At first these were ignored; but a time has come when this method of disposing of them is no longer possible. Thus, to quote Wright again:—

"I confess to having shared the conviction that immunisation is always strictly specific. Twenty years ago, when it was alleged, before the Indian Plague Commission, that anti-plague inoculation had cured eczema, gonorrhoea, and other miscellaneous infections, I thought the matter undeserving of examination. I took the same view when it was reported in connection with anti-typhoid inoculation that it rendered the patients much less susceptible to malaria. Again, some years ago, when applying pneumococcus inoculations as a preventive against pneumonia in the Transvaal mines, I nourished exactly the same prejudices. But here the statistical results which were obtained in the Premier Mine demonstrated that the pneumococcus inoculations had, in addition to bringing down the mortality from pneumonia by 85 per cent., reduced also the mortality from "other diseases" by 50 per cent. From that on we had to take up into our categories the fact that inoculation produces in addition to "direct" also "collateral" immunisation. This once recognised, presumptive evidence of collateral immunisation began gradually to filter into our minds. . . . From such cases hints are conveyed to us that there may exist a useful sphere of application for collateral immunisation; . . . we should discard the confident dogmatic belief that immunisation should be strictly specific, and that we should in every case of failure endeavour to make our immunisation more and more strictly specific. We should instead proceed upon the principle that the best vaccine to employ will always be the vaccine which gives on trial the best immunising response against the microbe we propose to combat."

The present position of non-specific therapy is explained in a recently published volume by Dr. Petersen of Chicago,[1] from which the above quotation from Wright is taken. When we come to inquire into the rationale of the procedure, we find that a theoretical basis to account for the results has been lacking,—the treatment has been empirical. With Petersen, we may perhaps put the matter broadly thus: the reaction of the body is fundamentally the same in all cases of injury; there is an effort to dilute the noxious agent (increased flow of lymph), to remove it (phagocytosis by leucocytes), to neutralise it (manufacture of antibodies); these failing, to wall it in. We may, in trying to influence this process, adopt one of two avenues of approach; we may proceed against the cause of the inflammatory reaction by fostering the production of an antibacterial agent or an antitoxin; treatment on these lines must necessarily be specific, must be directed against the particular micro-organism or toxin. Or we may endeavour to alter the inflammatory reaction of the body itself,—to stimulate the potential forces, latent or held in abeyance until the non-specific stimulation brings them into activity. This is somewhat vague; Wright has, in a recent lecture (see the *Lancet*, May 6), described one way, at least, in which the activation works. He has discovered that "the intravenous injection of a vaccine is immediately followed by the appearance of bactericidal substances in the blood, which are not specific but can act upon various types of organisms. . . . The late result of an inoculation with, say, a typhoid vaccine, is the production of antibodies which are specific for the typhoid bacillus, but the immediate result of such an inoculation is the appearance of non-specific antibodies. Inasmuch as leucocytes possess the power of inhibiting the growth of organisms on culture media, it seems likely that these non-specific substances exist ready-formed in the leucocytes which yield them in response to the immediate demand."

[1] Protein Therapy and Nonspecific Resistance. By Dr. William F. Petersen. Pp. xviii+314. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1922.) 21s. net.

Already a large number of substances have been used as non-specific agents; in many cases, of course, these remedies were employed long before any explanation of their action had been formulated on the above lines. Of the long list of agents given by Petersen only a few can be mentioned.

First comes counter-irritation by means of thermo-cautery, seton, blisters, etc. Each of these procedures has for object the production of a focus of inflammatory exudation, suppuration, or necrosis; the absorption of the pathological exudates must lead to a tissue stimulation similar to that which follows more modern non-specific injections. Our non-specific therapy is thus but part and parcel of this older practice of counter-irritation.

Normal animal sera have been used,—horse, beef, goat, sheep, chicken, and other sera; these were first injected subcutaneously, and in more recent years into a vein; as much as 250 c.c. of beef serum have been given in anthrax without injury. Antibacterial sera and antitoxins have been widely used,—diphtheria and tetanus antitoxin, antistreptococcic, antipneumococcic, antidysenteric serum, etc.;—as remedies, that is, not in the homologous diseases, but in other morbid conditions, *e.g.* diphtheria antitoxin against streptococcus infection, tuberculosis, lupus, etc. The numerous vaccines, prepared in the first place as specific agents,—typhoid, dysentery, streptococcal, pneumococcal, influenza vaccines,—have also been used with a non-specific object.

Various native proteins have been given,—solution of egg albumen and serum albumen injected subcutaneously, milk by intramuscular injection, casein, gelatin; of protein split products, proteoses (albumoses) prepared from different proteins sometimes give a very prompt and satisfactory reaction. The enzyme treatment of cancer, exploited some years ago, consisted in the subcutaneous injection of a trypsin solution; a general reaction,—chill, sweating, and rise of temperature,—followed the injection, and the patient would have several days of comparative comfort.

Colloidal metals constitute another group of remedies; these are active catalytic agents, and it is supposed that they act therapeutically in virtue of this property as inorganic ferments; they whip up the organism, which responds, if response is possible, by producing more leucocytes. A number of colloidal metals have been prepared for therapeutic employment; the colloidal silver preparations have been in use longest, but arsenic, zinc, gold, manganese, iron, mercury, and other metals, as well as sulphur and iodine, have been employed with varying success in septic conditions, endocarditis, rheumatism, trench fever, etc.

The use of light, Röntgen rays, and radium must also be mentioned. These agents first stimulate tissue cells, and later, with prolonged exposure, cause their death. In both cases substances enter the blood stream which produce a general reaction; this may be mild, or accompanied by severe fever. After moderate reactions of this type, if the patient is in good condition and able to respond, improvement of appetite, nutrition, and general well-being may set in, just as after other non-specific agents. Here, then, we have at least a partial explanation of the effect of heliotherapy in tuberculosis, as used, for example, at Leysin in Switzerland, of which the public has heard much in the last few months.

About half of Dr. Petersen's book is occupied with an account of the methods used and the results obtained in the numerous diseases for which non-specific therapy has been tried. The last chapter, on indications and contra-indications, gives much useful advice. We are reminded that the method can only be applied intelligently if we recognise that by it all the forces of cellular and humoral resistance are for a short period of time keyed to the highest pitch; stimulation of this kind is useless when the cells of the body are profoundly fatigued, and hence injections must be given early in the course of the disease. But "the non-specific method of treatment should under no circumstances be considered as a rival or a substitute for the proven specific measures that we have at our command. That a non-specific factor is at times and possibly often associated with the specific reaction may be true, the more reason that both should be studied and both utilised in their proper time and place."

The bibliography runs to no less than fifty pages, and must, one would think, be complete up to date. The book as a whole forms an interesting, convenient, and comprehensive account of a recent development of medical thought and practice.

The Solvay Institute of Chemistry.

THE first meeting of the "Institut International de Chimie Solvay" was held in Brussels on April 20-27, under the presidency of Sir William Pope. It will be remembered that before the war M. Ernest Solvay set aside a capital sum to be expended in the course of thirty years by the International Institute of Physics, and that meetings under the auspices of this Institute have been held in Brussels both before and since the war. More recently M. Solvay has set aside a further capital sum of one million francs, also to be expended in thirty years, for the promotion of the science of chemistry.

The meetings of the Institute are attended by delegates from different countries, the number being limited to about thirty, so that the discussions may be as free and as informal as possible. The recent meeting was devoted to the consideration of a number of those questions which affect the foundations of modern chemistry, and its programme included the presentation of papers on isotopes, by Soddy, by Aston, and by Perrin and Urbain; on X-ray analysis and molecular structure, by W. H. Bragg; on the electronic theory of valency, by Mauguin; on optical activity, by Pope and by Lowry; and on chemical mobility, by Job.

In connection with the papers on isotopes, considerable discussion was aroused as to the possibility of two dissimilar arrangements of planetary electrons around the same type of nucleus. The possibility of such an isomerism in the external domain of the atom was conceded, although at present only as a hypothesis;

but, in view of the fact that radiation by the atom is attributed to the movement of electrons from one orbit to another, the prospect of realising two different stable configurations of the orbits appears somewhat remote. Another possibility, that atoms may exist of equal atomic weight as well as of equal atomic number, has been discussed in connection with certain members of the radium and actinium series or radio-elements. The supposed necessity for recognising this subtle type of distinction between atoms is based on the assumption that radium and actinium are derived from a common parent and that all the members of both series of radio-elements must therefore have atomic weights of the type $(238-4n)$. If, however, radium and actinium are derived from isotopic forms of uranium, the two series of radio-elements may well prove to differ in atomic weight, *e.g.* by one unit. The discussion on Aston's paper dealt largely with the question of how an "element" should be defined, in view of the discovery of isotopes not only amongst radio-elements but also amongst the common elements. Aston appeared to voice the feeling amongst physicists by suggesting that each atomic number should represent one element; but he was opposed by a number of chemists, who argued that the word "element" carried with it an idea of homogeneity which could not be reconciled with the proposal to describe as an element a mixture of isotopes, the separation of which might at any time become a practical possibility. The paper on the separation of isotopes, presented by Perrin and Urbain, was to have been prepared by the late Prof. Guye. It certainly served to emphasise the extreme difficulty of the separation, since nearly all the methods derived from analogy with rare earths or isomeric hydrocarbons have been shown, both by theory and by experiment, to be impracticable.

Bragg's demonstration of recent results obtained by the X-ray analysis of crystals was greatly aided by models, which could be not only viewed at close quarters, but handled and studied during the whole period of the conference. Some discussion arose in connection with his demonstration of the relationship between the crystal structure of diamond and of graphite, and of the two kinds of relationship between carbon atoms which are shown by the model of graphite. Two different kinds of linkage were also shown between atoms of bismuth, corresponding perhaps to co-valence and electro-valence respectively. The principal subject of discussion arose, however, from the application of X-ray analysis to organic compounds and a bewildering array of chemical problems was suggested, in connection with which X-ray analysis might lead to useful results. A modification of Barlow and Pope's theory of crystal structure, in which a quadrivalent atom is represented by an aggregate of four unit spheres, was described, and shown to present many points of close agreement with the crystalline structure actually recorded in organic compounds.

The discussion on the electronic theory of valency which followed Mauguin's paper included perhaps a larger proportion of adverse criticism than is usually accorded to it. In particular, the lack of any adequate explanation of variable valency, and the indeterminate character of the valency equations (which do not admit of a unique mathematical solution) were the subjects of much comment.

The discussion on optical activity dealt mainly with the usefulness or otherwise of retaining the idea of the asymmetric carbon atom. It was agreed that the asymmetry of the molecule was the only thing that mattered; but expression was given to the view that the term was of value as enabling the organic chemist to recognise at once the existence of many cases of molecular asymmetry, although this might still be looked for in many cases where no asymmetric atom was present. In the discussion on rotatory dispersion the idea was expressed that liquid media which gave rise to complex dispersion-curves might be suspected of containing more than one type of optically-active molecule; in the case of coloured compounds, however, a looped curve might result from the presence of an absorption band in the region under investigation.

The discussion on chemical mobility was for the most part focussed on the radiation theory of chemical action. The lack of agreement between the predictions of the theory, and the results obtained in seeking to verify it, was emphasised. Thus, the observed temperature coefficient of the thermal dissociation of phosphine leads to the conclusion that an absorption band should appear in the violet region of the spectrum. No such band is found, and the theory has therefore been modified in a way which suggests that the active radiations may be found at lower frequencies, *e.g.* in the infra-red region of the spectrum. Actually, however, the change is very sensitive to ultra-violet radiations, and a further modification of the theory would be needed to account for this persistent deviation from the experimental facts.

Universal Wireless Telephony.

In view of the great technical progress that has been made during the last few years in the development of the wireless telephone, and the attention that has been given by the Postmaster-General to the framing of regulations for its orderly use in this country, a considerable popularisation of wireless telephony appears imminent. It is therefore of some interest to examine briefly the facilities as well as the limitations which exist regarding its use. It is obvious that anything like secrecy in conversation over the radio-telephone, as it is now often called, is out of the question, as any one in possession of a half-guinea licence and a receiving set, which can be tuned to the wave-length employed, can "listen in" and pick up the message irrespective of the station for which it was primarily intended. On account of the publicity which thus attends the utterances of the wireless telephone, its field, except in such special cases as aeroplane work, is practically limited to the dissemination of public information, news, music, and other entertainment items, or as it is now commonly called, "broadcasting." Unless, however, these broadcasting stations are rigorously controlled, they will not only defeat their own ends by drowning each

other's messages in a confused babel of sounds, but will interfere with other forms of radio-communication, as already happens to a considerable extent in America.

The most important consideration is that of wave-length, as simultaneous messages at or near the same wave-length mutually "jam" one another, and it may be mentioned that the margin of wave-lengths within which wireless telephone apparatus can be made to "tune out" other messages is not so fine as it is with the best class of wireless telegraph receivers. In order to avoid interference with other established services, the Post Office has allotted the range of 350 to 425 metres to the broadcasting stations. In this connection it should be recalled that the greater part of ship and shore Morse communication is on a 300 to 600 metre wave, and that amateur stations are allowed a wave-length of 440 metres. The well-known Writtle station will work in future at 400 metres, and the Air Ministry wave-lengths are 900 metres for the Croydon aeroplane service and 1400 metres for long-range weather reports, etc., while most of the powerful stations use longer waves up to the 2500 metres of the Eiffel Tower. Possibility of interference will also be limited by allowing broadcasting only between the hours of 5 and 11 P.M. on week-days or any time on Sundays.

Further considerations are the locality and range of the transmitting stations. To avoid too much overlapping, one station will probably be allowed at each of the following points: London, Cardiff, Plymouth, Birmingham, Manchester, Edinburgh, Glasgow, and Aberdeen, and arrangements will be made between the licencees at these stations as to wave-lengths and times of operation within the allotted limits.

With the view of circumscribing to some extent the field of each station, its power will be limited to that corresponding to an input of 1½ kw. The actual distance over which a station can be heard, however, depends more on the receiving than on the transmitting apparatus, but with modern delicate equipment an approximate idea of the possible working range is given by taking about ½ mile for every watt input. Thus, although a simple set may only be able to hear the nearest of such a group of stations, a really sensitive set, say in London, could readily pick up all of them.

The cost of a receiving set for private use in picking up whatever programmes are to be broadcasted, varies considerably with its sensitiveness. Roughly, the minimum that need be expended will depend on the distance from the nearest public station, assuming that to be the only one the owner desires to hear. A set of this kind with a range of 25 miles or so would cost from 5*l.* to 10*l.* complete with the simple aerial that would be necessary. Actually, however, the cost of the equipment selected for any particular case will depend upon whether the apparatus is required to be used to pick up waves from longer distances as well, such as to hear the wireless concerts already being radiated from the Hague, and the time and other signals from the Eiffel Tower. In this case a detector of the thermionic valve tube type must be employed, with one or more degrees of amplification and a greater range of tuning inductances, etc., and a multicell dry battery or other source of voltage for the tubes, as well as the two-cell accumulator, which would otherwise be sufficient. A moderately sensitive apparatus of this kind, with a range of 75 miles or more, would cost about 20*l.*, and further requirements of sensitivity could easily bring the price to, say, 75*l.* Another point influencing the cost of the equipment is the class of aerial which it is convenient to use, as the more sensitive the set the smaller is the aerial with which it will work over a given distance. As a rule, the simple crystal set will require some form of outside aerial, whereas the more delicate set with amplifying valves will give surprising results with a portable aerial, inside a room, composed of a few turns of wire on a rectangular frame.

Although probably the best results are obtained with these sets by the use of headpiece telephones, loud-speaking sets, audible to a number of persons at once, can be used with all the better-class apparatus, and this feature will doubtless add greatly to the popularity of wireless telephone reception.

A number of firms are devoting themselves to the manufacture of this kind of apparatus, including, of course, such well-known establishments as the Marconi Co. The Radio Communications Corporation is also well to the fore, and, as we have already announced, special arrangements are being made at the Trafford Park Works of the Metropolitan-Vickers Electrical Co. Other firms specialising in wireless receiving apparatus suitable for these purposes include Radio Supplies, C. F. Elwell, Ltd., and the R.M. Radio Company. We hope before long to have the opportunity of publishing some particulars of the actual apparatus made by some of these firms.

Obituary.

T. Sandmeyer.[1]

Traugott Sandmeyer, well known to all chemists as the discoverer of the reactions which bear his name, was born at Wettingen in Aargau in 1854. Left an orphan by the death of his father the day after his birth, his mother had to resume her former occupation as a school teacher. His father, who was a science teacher, left a library of scientific books, the perusal of which led young Sandmeyer to interest himself in scientific apparatus, and after spending some time in an engineering workshop, entered the employment of Mr. J. F. Meier, of Zurich, a manufacturer of physical apparatus. Sandmeyer afterwards started business on his own account, and supplied apparatus to the Polytechnic institution. He became in this way connected with the staff of the institution, and in 1882 was appointed lecture-assistant to Victor Meyer.

The story is often told how Victor Meyer, in attempting to show his class what was then known as the "indophenin reaction" with coal-tar benzene, used benzene obtained by distilling calcium benzoate with lime and failed to produce the expected result. It is

[1] This account is mainly gathered from an interesting obituary notice by Dr. Fierz in the issue of the Journal of the Society of Chemical Industry for May 15.

not so well known that Sandmeyer directed the attention of the professor, who had forgotten the incident, to this remarkable difference between the two kinds of benzene, which subsequently led to the discovery of thiophene and its numerous congeners. When Prof. Meyer was transferred to Göttingen in 1885, Sandmeyer accompanied him, but very shortly returned to Zurich, where he became assistant to Prof. Hantzsch. In 1888 he joined the firm of J. R. Geigy, manufacturers of dyestuffs of Basle.

Apart from the Sandmeyer reactions and his remarkable synthesis of indigo from thiocarbanilide in 1899, Sandmeyer's discoveries are little known to chemists unconnected with the synthetic dye industry, in which his later activities lay, and where his greatest successes were achieved. He was a man of reserved habits and made few friends outside the small coterie of his collaborators and fellow-workers, but is described by one, formerly associated with him, as a colleague who was always ready to help and advise. His skill as an expert mechanician, his scrupulous care as an experimenter, and his powers of observation often led him to discoveries which others had overlooked, and the long list of new and valuable dyestuffs of which he was the author placed him in the forefront of colour chemists.

In recognition of his work the University of Heidelberg conferred upon Sandmeyer the degree of Ph.D. *honoris causa* in 1891, and in 1915, at the celebration of the 150th anniversary of the firm of J. R. Geigy Co., of which he had meantime become a director, he was made an honorary doctor of the Zurich Technical School. On his retirement in 1919 Sandmeyer left a large portion of his wealth to the pension fund of the firm with which he had been so long associated.

PROF. H. M. HOWE.

PROF. HENRY MARION HOWE, whose death was recently announced, in his seventy-fifth year, was the doyen of American metallurgists. He was well known both here and on the Continent. He was born at Boston on March 2, 1848, the son of Dr. Samuel Gridley Howe, who was one of the earliest to assist the Greeks in their struggle for freedom. His mother, Mrs. Julia Ward Howe, was the author of the famous "Battle Hymn" of the Republic.

Prof. Howe graduated at the University of Harvard in 1869 in arts, and two years later in science at the Massachusetts Institute of Technology. He then engaged in metallurgical work in Pittsburg, Pa., and Troy, N.J., and soon became known as a keen observer and investigator. In 1880 he designed and built the works of the Orford Nickel and Copper Company at Capeltown in the province of Quebec, and at Bergenpoint, N.J. From 1883 to 1897 he resided at Boston, and set up in private practice as a consulting metallurgist and expert witness in metallurgical patent suits. With this he combined the position of lecturer on metallurgy at the Massachusetts Institute of Technology. He was an original member of the American Institute of Mining Engineering, founded in 1871, and soon contributed to its transactions. His first paper was on "Blast-furnace Economy," which was followed by "Thoughts on the Thermic Curves of Blast-furnaces" and "Nomenclature of Iron," the latter a remarkable contribution to the discussion inaugurated by A. L. Holley in his famous paper, "What is Steel?" His first book, published in 1885, dealt with copper smelting. This was followed in 1891 by "The Metallurgy of Steel," a book which did much to lay the foundations of scientific steel metallurgy, and created for him an international reputation in the subject.

In 1897 Prof. Howe was called to the chair of metallurgy at Colombia College, New York, a position which he filled for some fifteen years. On his retiring to become a consulting metallurgist, he was appointed professor emeritus. He was one of the small band of metallurgists who helped to lay the foundations of the science of metallography, and his name will always be remembered in connection with those of the late M. Osmond, Martens, H. Le Chatelier, Tschernoff, Anossov, Stead, Roberts-Austen, and Arnold. In this connection, his principal contribution is his book entitled "The Metallography of Steel and Cast-iron," a monumental work, which displays a remarkable grasp of the subject and an unusual power of weighing scientific evidence. Prof. Howe was not primarily an experimentalist, although in his later years he published several papers with the late A. G. Levy, dealing particularly with the iron-carbon equilibrium. He was, however, a prolific writer, and in all published more than 300 papers. He was vice-president of the Taylor Wharton Iron and Steel Company, and introduced the manufacture of manganese steel into the United States in 1890.

Prof. Howe was president of the American Institution of Mining Engineers, honorary vice-president of the Iron and Steel Institute, chairman of the engineering division of the National Research Council, consulting metallurgist of the U.S. Bureau of Standards, and research associate of the Carnegie Institution of Washington. Many honours came to him from various countries. In 1895 he was awarded the Bessemer Medal of the Iron and Steel Institute, later the Elliot Cresson gold medal of the Franklin Institute, a special prize and gold medal from the Société d'Encouragement pour l'Industrie Internationale, and finally, in 1917, the John Fritz gold medal, the highest honour in the gift of the engineering institutions of the United States of America. He also received several foreign orders, including the Legion of Honour and the Russian order of St. Stanislas. Prof. Howe was a frequent visitor to this country, and his genial personality will be greatly missed by metallurgists over here.

DR. ROBERT BRUCE-LOW.

DR. ROBERT BRUCE-LOW, the distinguished epidemiologist, died on May 11 after a brief illness. Born in Edinburgh in 1846, he was educated at the Royal High School and University of that city, and graduated in medicine in 1867. After a year spent in post-graduate study in London and Germany, he settled down as a general practitioner, first in Lincolnshire and afterwards at Helmsley in the North Riding, becoming the medical officer of health of the latter district.

This nineteen years of general practice gave him

an insight into the conditions of rural hygiene which was most useful to him in after life. So valuable did the central health authority of those days consider Bruce-Low's work in Helmsley that he was invited in 1887 to become a medical inspector of the Local Government Board, an invitation which he readily accepted. Here he came into intimate association with Buchanan, Thorne-Thorne, and Power, who, as successors to John Simon, were engaged in building up the English public health service. Bruce-Low conducted several inquiries and wrote many important reports for the Local Government Board, the best known of which are those on the progress and diffusion of plague, cholera, and yellow fever, the epidemiology of typhus fever, acute anterior poliomyelitis (1916), and smallpox (1918). Through his epidemiological studies Bruce-Low acquired an intimate knowledge of port sanitary administration, and in reply to an inquiry, furnished the Rockefeller Institute with a statement on the facts which led to the abandonment of quarantine in the United Kingdom. After holding many examinerships for the diploma of public health, he was appointed by the General Medical Council their Inspector of Examinations for degrees and diplomas in public health, work which occupied him for the greater part of the last two years of his life, and the outcome of which was a valuable report and a revised scheme of examination, now under consideration. Bruce-Low became assistant medical officer of the Local Government Board in 1900, retiring in 1911. He served on the War Office Anti-typhoid Inoculation Committee, 1904–12, and on the outbreak of war he was recalled to the Local Government Board, finally retiring in 1920.

Bruce-Low was always ready to help his colleagues, to whom he was a true friend; he was proud of being a Civil Servant, and his distinguished services to his country and to the science of preventive medicine were officially recognised in 1919, when he was appointed C.B.

R. T. H.

WE notice with much regret the announcement in the *Lancet* of the death, on May 18, of Prof. Charles Louis Alfonse Laveran, Foreign Member of the Royal Society, at the age of seventy-six years.

Current Topics and Events.

THE Royal Academy of Belgium celebrated the one hundred and fiftieth anniversary of its foundation on May 23 and 24 in the presence of a large number of its members and of delegates from other academies and learned institutions. On the Wednesday afternoon, May 24, numerous congratulatory addresses were presented at the Palais des Académies, and the members and visitors were afterwards received at the Hôtel de Ville by the Mayor of Brussels, M. Adolf Max, and his Aldermen, MM. Steens, Vande Meulebrouck and Coelst; a reception was held at the Palais des Académies in the evening, where an exhibition of medals and portraits connected with the history of the Academy had been arranged. The anniversary celebration itself was held in the large hall of the Academy on the afternoon of May 25 in the presence of the King, the Minister of Arts and Science, M. Hubert, formerly Rector of the University of Liége, Cardinal Mercier, and the English, French, Dutch, Spanish, and Japanese Ambassadors. The president, M. Vauthier, in an address of welcome, briefly sketched the history of the Academy and its influence on the intellectual development of Belgium. The Minister of Justice, M. Masson, tendered the congratulations of the Belgian Government, and Monseigneur Baudrillart spoke in the name of the Institut de France. Sir William B. Leishman, as vice-president of the Royal Society, represented the British universities and learned societies; he referred to the activities of Belgian bacteriologists and paid a high tribute to the work of M. Jules Bordet. MM. Lameere, Pirenne, and Verlant, representing respectively the classes of science, of letters, and moral and political sciences, and of fine arts, contributed summaries of the activities of their several sections of the Academy. Later the visitors were received by the King and the Queen at the Palace of Laeken, and in the evening a banquet was held at the Hôtel Astoria.

THE Council of the Museums Association has addressed an emphatic protest to the Prime Minister against the proposal to reinstitute charges for admission to the National Galleries and Museums. It is only in recent years that the importance of Museums and Art Galleries as factors in the educational machinery of the country has been fully recognised, and this is due largely to the progressive action of the Government in advocating consistently the policy of free admission and in providing guides which have advanced materially the popularity and usefulness of our National Institutions. The Association feels that the proposed reversal of a policy adopted after many years' experience will be a serious set-back to Museum work, both in regard to the wider education of the nation and the provision of wholesome recreation for the people. If the proposal is adopted it is bound to have an influence on the policy of provincial Museums, the governing bodies of which are largely influenced by the example set by the State. The Association suggests that the far-reaching injury likely to follow the imposition of admission fees would greatly outweigh the small additional income, 10,000*l*., which is expected to accrue.

THE highly controversial subject of the college-trained engineer was chosen by Prof. Frederic Bacon for his presidential address to the Swansea Engineering Association of Students of the South Wales Institute of Engineers. Prof. Bacon had a good deal to say about the conditions which the student is likely to find in works after he leaves college, and the kind of experience which he will then acquire. One of the least satisfactory features of the pre-war position was that scarcely any British firms were undertaking new development work; nearly every innovation in engineering practice was imported from the continent or the United States, a state of affairs

extremely damaging to the prestige of British engineering and very unfair to the scientifically trained engineers of this country. The war showed the capabilities of British men of science and engineers when they work hand in hand and with the necessary resources placed at their disposal. It is the duty of college-trained men to show their faith in science, and to champion her cause when it is unfairly attacked by men who are ignorant of her methods and mission. The engineer can never lose sight of utilitarian ends, but he should know enough of the spirit of science and the recent history of industry and invention to respect and encourage the work of the investigator in pure science.

THE third International Congress of the History of Medicine will be held in London on July 17 to 22 inclusive. The congress will be opened at 10.30 A.M. on July 17 by the Minister of Health at the Royal Society of Medicine, where the delegates will be received and an address will be delivered by the president, Dr. Charles Singer. In the afternoon there will be a reception and an address by Sir Norman Moore, President of Honour, at the Royal College of Physicians. In the evening the President and Mrs. Singer will receive the members of the congress at the Royal Society of Medicine, when an address will be given by Prof. Elliot Smith. The sessions of the congress will be held on the following days from 10.30 A.M. to 12.30 P.M., and from 2.30 P.M. to 4.30 P.M., at the Royal Society of Medicine. A committee of ladies has been organised to conduct ladies attending the congress to various places of interest in London. The Wellcome Historical Museum, 54A Wigmore Street, where a special exhibition will be held, will be open from 10 A.M. to 5.30 P.M. daily. Objects of interest will also be on view in the library of the Royal Society of Medicine. Arrangements have been made for visits to the Royal College of Surgeons, the Society of Apothecaries, the Barbers' Hall, St. Bartholomew's Hospital, and other places of medico-historical interest. Further information can be obtained on application to the general secretary, Dr. J. D. Rolleston, 21 Alexandra Mansions, King's Road, S.W.3.

EXCEPTIONALLY hot weather for the time of year was experienced over the south-eastern and central portions of England on the four days from May 21 to 24, and record temperatures occurred in many places. At the Royal Observatory, Greenwich, observations of the highest order are obtainable for the past 80 years, since 1841, and approximately trustworthy observations can be obtained for as far back as 1814, embracing in all a period of 109 years. In the recent hot spell the sheltered thermometer at Greenwich registered 90°·2 on May 22 and 90°·6 on May 24. The previous records for May since 1841 show only eight days with a temperature so high as 85°, the maximum being 87°·5 on May 26, 1880, followed by 87°·0 on May 19, 1868, and 86°·5 on May 25, 1920, while a temperature of 90° has occurred only seven times during June since 1841, and once only since 1897. The mean maximum shade temperature for the four consecutive hot days was 88°·8, and the mean solar radiation temperature was 148°·5, the maximum being 151° on May 23. In May 1913 there were five consecutive days with the temperature above 80°, the highest temperature being 84°·1 and the mean for the period 82°·2; this is the record for consecutive hot days and also for the number of hot days in the month, the total days being five, the same as this year, which includes May 8 last. In 1870 there were four consecutive days with the temperature above 80°, the mean for the four days being 82°·4. On three consecutive nights during the hot spell the minimum temperature was above 58°, the temperature on the warmest night being 58°·9, and the lowest temperature for four days was 57°·9. Previous records from 1841 show three instances only of warmer nights, 61°·5 on May 25, 1841, 61°·3 on May 24 and 60°·3 on May 29, 1847. The mean daily temperatures at Greenwich for the three days May 22 to 24 were 74°·5, 73°·5, and 74°·8 respectively, which is 20° above the average. The previous highest day mean in May since 1841 was 71°·3 on May 28, 1841, and going back to 1814 the highest day mean was 72°·4 on May 15, 1833. Since the extreme heat of 90°·6 at Greenwich on May 24 the day temperatures steadily decreased, reaching 73° by the end of the week. Thunder-storms accompanied by a heavy fall of hail and rain were associated with the recent hot spell.

AT the annual general meeting of the Institute of Physics held on May 23 in the rooms of the Royal Society, the following Officers and Board were elected to serve for the year beginning October 1, 1922: *President*, Sir J. J. Thomson; *Past-President*, Sir R. T. Glazebrook; *Vice-Presidents*, Sir Charles Parsons, Prof. W. Eccles, Prof. C. H. Lees, Mr. C. C. Paterson; *Non-Official Members of the Board*, Dr. R. S. Clay, Prof. C. L. Fortescue, Prof. A. Gray, Major E. O. Henrici, Sir J. E. Petavel, Dr. E. H. Rayner, Sir Napier Shaw, Mr. R. S. Whipple; *Representatives of Participating Societies:* Physical Society—Mr. C. E. Phillips, Mr. F. E. Smith; Faraday Society—Mr. W. R. Cooper; Optical Society—Mr. John Guild; Röntgen Society—Dr. G. W. C. Kaye; Royal Microscopical Society—Mr. J. E. Barnard. The Annual Report stated that there were 408 Members of the Institute at the end of the year, of whom 258 were Fellows. The Institute is watching the possibility of establishing a central library for physics, although the financial difficulties in the way of its realisation are stated to be considerable. In the course of his presidential Address, Sir J. J. Thomson, after dealing with the project to establish a Journal of Scientific Instruments, spoke of the present depression in industry, but he made the reassuring statement that out of 67 students who graduated with distinction in physics and chemistry in 1921, 46 had obtained suitable positions, while 14 were doing research work. He hoped that the series of lectures on physics in industry which had been established would act to some extent as "Refresher Courses." Speaking of the difficulties which

the Safeguarding of Industries Act had, in many instances, placed in the way of research, he characterised research itself as a "Key Industry," and he hoped that the Government would put every facility in the way of research workers to enable them to obtain without delay the apparatus they required.

THE idea of establishing an International Hydrographic Bureau was suggested some years before the war, and the project took definite shape when the Admiralty called an International Hydrographic Conference in London in July 1919. Twenty-four of the maritime states of the world were represented and steps were taken to establish a permanent bureau. A committee was appointed which, after nearly two years' work, devised an organisation that proved acceptable to the states represented. Captain Spicer-Simson, the secretary-general, gives some details regarding the Bureau in the *Geographical Journal* for April. The aim is to establish close and permanent association between the hydrographic services of various states, to co-ordinate their efforts with the view of rendering navigation easier and safer, and, so far as possible, to obtain uniformity in hydrographic documents. The Bureau is consultative only and has no authority over national hydrographic offices, which remain entirely independent. It will have a collection of all charts and works published by the various hydrographic and other offices, and will collect papers bearing on hydrography and navigation. An important duty of the Bureau will be the collection and distribution of information on the subject of hydrographic surveys and other publications which are being prepared in the various national offices, and it will also undertake the organisation of an International Hydrographic Conference, if possible, every five years. The Bureau is directed by a board, of which the present members are: Vice-Admiral Sir J. Parry, president; Rear-Admiral J. M. Phaff (Netherlands); Captain S. H. Müller (Norway), and Captain G. Spicer-Simson (Great Britain). The address of the Bureau is, 3 rue du Port, Monaco.

THE British Non-Ferrous Metals Research Association has just issued, in its Quarterly Bulletin, a Union List of periodicals of interest for reference on industrial metallurgy. The service provided by 14 libraries in London, Birmingham, and Manchester is clearly indicated, so far as concerns the 118 periodicals which have been selected. Since one of the main functions of the Industrial Research Associations is to serve as distributing centres for scientific and technical information to their members, such a key-index should prove of great value and will doubtless be followed by other bodies for their own special subjects. It may also be taken as an indication of the interest that is likely to be taken in the proposed World List of Scientific Periodicals of the Conjoint Board of Scientific Societies.

MR. HARRY ALLCOCK, in a pamphlet entitled "The Power of the Penny," advocates a system of decimal coinage of which the shilling would be the unit, divided into ten pennies of a new series, each of which would be worth $1\frac{1}{5}$ of the existing penny; in other words, an existing sixpence would represent five of the new pennies. His view is that the present time is specially favourable for a reform of this kind, which would contribute to the reduction of postal and other charges, which have been raised from 1d. to $1\frac{1}{2}$d., to a penny of the new issue. One thing is obvious, that the currency is at present in an unsatisfactory condition requiring the careful consideration of experts, and the possibility of adopting a decimal system might well form part of such an inquiry. Mr. Allcock has not dealt with the question of fractions of a penny. Each of his new pennies would have to be divided into ten smaller coins, representing $\frac{3}{25}$ of the existing penny in value: in other words, the old-fashioned halfpenny would have to give place to a new coin of higher value.

THAT well-known optical toy, the kaleidoscope, is occasionally used to illustrate the principles of reflection and to study symmetrical patterns. A simple modification has appeared under the name of a "patternscope" in which two metallic reflectors and a glass window form the three sides of a hollow triangular prism about 3 in. long and closed at both ends. A number of small curvilinear pieces of celluloid and glass of different shapes and colours are enclosed, which together with their reflections form an endless variety of beautiful patterns which can be seen through the window more comfortably than is possible through the eyepiece of the kaleidoscope, and also can be seen by more than one person at one time. Either end of the prism may be used as the base, each having a different coloured design on the inside and so adding to the number of patterns obtainable. The instruments are sold by Messrs. "Patternscopes," 85 Duckett Road, Harringay, London, N.4.

DR. L. SILBERSTEIN, mathematical physicist of the Research Laboratory, Eastman Kodak Company, has been appointed an associate editor of the Journal of the Optical Society of America.

SIR WILLIAM PHIPSON BEALE, who died on April 13 last, bequeathes, on the death of his wife, sums of 5000*l*. and 200*l*. to the Royal Institution of Great Britain and the Mineralogical Society respectively.

DR. GORDON HOLMES will deliver the Croonian Lectures of the Royal College of Physicians of London, on Tuesdays and Thursdays, June 8, 13, 15, 20, at 5 o'clock, at the College, Pall Mall East. His subject will be: "The Symptoms of Cerebellar Disease and their Interpretation."

AT the anniversary meeting of the Royal Geographical Society held on May 29, the following officers were elected: *President*: Lord Ronaldshay; *Vice-presidents*: Sir Francis Younghusband, Col. Sir Charles Close, Dr. D. W. Freshfield, Lord Edward Gleichen, Sir T. H. Holdich, and Sir J. Scott Keltie;

Treasurer: Mr. E. L. Somers Cocks; *Trustees*: Lord Curzon of Kedleston and Mr. H. Yates Thompson; *Hon. Secretaries*: Dr. A. P. Maudslay and Lieut.-Col. E. M. Jack; *Foreign Secretary*: Sir Maurice de Bunsen; *Members of Council*: Mr. Henry Balfour, Prof. R. Beazley, Sir Sidney Burrard, Mr. Oliver Bury, Lord Chelmsford, Prof. J. Norman Collie, Sir W. Martin Conway, Sir C. L. Des Graz, Sir Henry Galway, Sir Sidney Harmer, Dr. D. G. Hogarth, Col. C. K. Howard Bury, Admiral Sir Edward Inglefield, Mr. P. Lake, Sir Henry McMahon, Prof. J. L. Myres, Capt. C. W. R. Royds, Major-Gen. Sir Frederick Sykes, Brig.-Gen. Sir Percy Sykes, Dr. A. F. R. Wollaston, and Mr. J. M. Wordie.

MESSRS. DULAU AND CO., LTD., 34 Margaret Street, W.1, have just issued a catalogue (No. 93) of second-hand books in zoology offered for sale by them. Upwards of 3000 works are listed under the following headings: entomology and Arachnida; conchology and Mollusca; minor classes; general zoology; Mammalia, fishes, reptiles, etc.; ornithology and oology.

MESSRS. BERNARD QUARITCH, Ltd. (11 Grafton Street, W.1) have just issued a catalogue (No. 370) of important and rare second-hand books on natural history. Upwards of 2000 titles are listed under "General Works" and eleven classified divisions. Mr. F. Edwards (83 High Street, Marylebone, W.1) has just circulated Catalogue No. 431, which is largely devoted to publications of learned and scientific societies, and to works on the topography of the English counties.

Our Astronomical Column.

LARGE FIREBALL.—On May 21, at 12.32 G.M.T., a large meteor was observed by the well-known variable star observer, M. Felix de Roy, at Antwerp, Belgium. The object moved slowly among the stars of Leo, and left a tail of sparks like a rocket. Its path was from $169° + 9°$ to $155° + 18°$. The same meteor was observed by Mr. J. P. M. Prentice, at Stowmarket, and he recorded the path from $203° + 1\frac{1}{2}°$ to $179° + 15\frac{1}{2}°$. The duration was estimated at six seconds. Comparing the two observations the radiant point is indicated at $280° - 33°$ in Sagittarius. The height of the object was from about 60 to 57 miles and the velocity 15 miles per second. The meteor passed over the region from the south-west of Surrey to south of Warwick.

It is possible that the object radiated from Scorpio at $250° - 27°$, and that its height was 60 to 42 miles, but the observations are not quite conclusive, and more data are required.

COMETS.—There is great difference of opinion as to the magnitude of Skjellerup's comet; Dr. Steavenson makes it mag. 9; other observers, mag. 12. The following approximate orbit has been deduced from observations at Heidelberg, Yerkes Obs., and Milan, on May 20, 21, 22.

T 1922, May 19, 22 G.M.T.
ω 1° 15′ 55″
Ω 207 56 17
i 21 19 4
log q 9·94569

EPHEMERIS FOR GREENWICH MIGNIGHT.

	R.A. h. m. s.	N. Decl.	log r.	log Δ.
June 2	9 38 28	36° 34′	9·9638	9·5856
6	10 18 28	40 58	9·9747	9·5680
10	11 4 53	44 39	9·9871	9·5592
14	11 57 13	47 5	0·0011	9·5600
18	12 51 8	48 2	0·0161	9·5695

The comet should be looked for as soon as the sky is dark; its path lies through Lynx (near Alpha on May 30), Leo Minor, and Ursa Major (near Mu on June 6, near Psi on June 10). Mr. G. Merton points out that the orbit closely resembles that of comet 1830 I; identity does not seem to be possible, but the two comets are probably portions of a primitive single comet.

The Annals of Tokyo Observatory, Tom. v., fasc. 5, contains an investigation of the perturbations of Wolf's periodic comet from 1884 to 1918, by M. Kamensky, Director of Vladivostock Naval Obs., who has revised the work of M. Thraen, finding several small corrections, which produce a marked improvement in the comparison with observation. Definitive elements are given for each return, the perturbations by all planets except Mercury, Uranus, and Neptune having been computed. M. Kamensky notes that there will be a close approach of the comet to Jupiter at the end of 1922; "it will experience such large perturbations that it is doubtful whether its seventh return to the sun—provided that it takes place—will be capable of being connected with the six preceding ones by a common system of elements." It is interesting to note that Brooks's periodic comet (1889 V) also makes a close approach to Jupiter this year, about the middle of June.

Lick Observatory Bull. No. 334 contains an investigation by H. M. Jeffers of the orbits of the two components of Taylor's comet, 1916 I, which was discovered at Capetown on November 24, 1915, as a small nebulosity 20″ in diameter, with an eccentric nucleus. On February 9, Barnard found the comet to be double, the two components being 10″ apart; the northern component was at first fainter, but afterwards became the brighter, and remained visible for two months after the southern one had disappeared; the following are the definitive elements found for the two components; perturbations by Venus, Earth, Mars, Jupiter, Saturn have been applied. They are for the equinox of 1916·0.

Epoch and Osc.	Northern Component. 1916, Jan. 21, 0 G.M.T.	Southern Component. 1916, Jan. 21, 0 G.M.T.
M	− 1° 32′ 6″·4	− 1° 32′ 4″·9
ω	354 47 57·7	354 47 21·8
Ω	113 54 10·2	113 54 25·1
i	15 31 40·6	15 31 27·8
ϕ	33 7 29·6	33 6 36·6
μ	557″·274	557″·695
log a	0·535959	0·535740

The linear distance between the components was least at perihelion, when it was 0·000047 astr. unit. Four months later it was 0·000168. It is noted that in the case of Biela's comet the distance was a maximum at perihelion. The elements show some resemblance to those of Daniel's comet of 1909, but identity is not possible. Taylor's comet is due at perihelion about June 13, 1922, but the conditions are unfavourable for observation; it may, however, be detected in the autumn.

The splitting of Taylor's comet does not appear to have been caused by Jupiter; the nearest approach in the revolution preceding 1916 was 1·1 unit, which is scarcely close enough to explain disruption.

Research Items.

KNOTS IN ANCIENT EGYPT.—Miss M. A. Murray contributes to *Ancient Egypt* (Part I., 1922) an interesting article on the representations of various kinds of knots on early Egyptian monuments. It is a remarkable fact that in the early dynasties knots were never represented, but in the Middle Empire, though the same prejudice still existed, there was a movement towards an accurate presentation of the knot, showing that there was a change, and that the old ideas were beginning to pass away. Miss Murray does not propose an explanation of this curious taboo of the knot on the ancient monuments. It may be suggested that it was based upon the use of knots in magic. Among many races, knots, real or symbolical, are used as a magical means of obstructing some special action. Thus the use of knots at marriage is often disapproved. However this may be, the paper, with good illustrations of various forms of knots and their uses, is of considerable interest.

THE PILTDOWN SKULL.—An important contribution to the controversy over the Piltdown Skull was made by Profs. Elliot Smith and Hunter at a meeting of the Anatomical Society held on May 12, when they exhibited a reconstruction of the skull and its endocranial cast. The reconstruction has been made by a careful and minute examination and correlation of the anatomical points of the fragments of the skull. The result confirms generally the reconstructions made by Dr. Smith Woodward and Mr. Pycraft when first the skull was discovered, and agrees in showing the remarkable breadth of the skull and its low capacity, which is, in each case, placed below 1300 c.c. This later reconstruction, however, differs in one important particular. The occipital fragment assumes a more vertical position, with the effect that the skull is brought into closer relation with the skull of the anthropoids. As a result, the cranium falls into complete harmony with the chimpanzee-like jaw, and the paradox which has hitherto been a stumbling-block to the acceptance of the jaw as indubitably belonging to the fragments of the cranium now disappears.

SAND- AND MUD-BINDING PLANTS.—An interesting exhibit is made in Museum IV., at Kew, of plants used for binding sand and mud. Erosion of bare sand dunes and mud flats by wind and tide is so serious in some coastal regions that the services of engineers and forest officers are constantly engaged upon protective work. Violent winds disturb large quantities of sand, the contour of dunes is constantly changing, and sand encroaches upon cultivated land or is piled in positions that interfere with the domestic and business life of the people. Bare mud flats also undergo constant change by tidal action, and adjacent agricultural land is imperilled. Protective work takes the form of barriers to check scour, and the insertion of such plants as are capable of binding sand or mud. After sand dunes have been fixed by low, dense grasses, other plants soon appear, and the forester assists by planting pine trees, thereby changing desert areas into pleasant places of residence. Mud flats that become overgrown with coarse grasses collect debris and, rising gradually above high-water mark, are turned into rich pasturage. The most satisfactory sand binder is "Marram Grass" (*Ammophila arundinacea*) (Kew Bulletin, No. 9, 1913, pp. 363-366, "Marram Grass for Paper-making"), and the best grasses for binding mud flats are species of Spartina. Articles on Spartina in connection with coast erosion appeared in the same journal (No. 5, 1907, pp. 190-197, and No. 1, 1918, pp. 26-31).

ADDITIONS TO THE INSECT FAUNA OF BRITAIN.—Recent issues of the *Entomologist's Monthly Magazine* contain records of several interesting and, in some cases, important additions to the insect fauna of Britain. In the March number, Mr. K. G. Blair mentions the occurrence of the beetle *Carpophilus ligneus*, Murray, in several widely separated localities, ranging from the Isle of Wight northwards to Liverpool. In each case it was discovered associated with merchandise. The species was originally described from Mexico, and has also occurred in Central America, but does not appear to have been noticed hitherto in Europe as a possible pest of commerce, although its congener, *C. hemipterus*, L., is an almost cosmopolitan species affecting dried fruits and other provisions. In the April issue, Mr. H. St. J. Donisthorpe records the beetle *Nebria iberica*, Oliv., which appears to have been confused hitherto with the very common *N. brevicollis*. Dr. G. Enderlein publishes in the May number of that same journal the description of a new genus and species of scaly-winged Psocids, specimens of which came from Crowborough, Sussex (F. J. H. Jenkinson). The insect, which he designates as *Pteroxanium squamosum*, belongs to a sub-family previously known only from New Guinea and Ceylon; the occurrence of a representative in Europe is therefore very remarkable and suggests the possibility that it is not indigenous but has been imported by some means or other. In the same issue Mr. F. W. Edwards describes a new genus and species of gall midge from North Sussex, the early stages of which are passed among bark-encrusting fungi, upon which blister-like swellings are caused. It appears to be the first record of an Cecidomyiid fly producing a fungus gall. Prof. F. V. Theobald, in *Bulletin of Entomological Research*, Feb. 1922, describes a new genus and species of aphid, *Laingia psammæ*, from marram grass and meadow foxtail in Kent. It was preyed upon by numerous ladybirds, particularly the common two-spotted species.

INCREASING THE SENSITIVENESS OF PHOTOGRAPHIC PLATES.—M. Clerc, in his "Paris Notes" in the *British Journal of Photography*, May 19, refers to M. F. Monpillard's success in 1912 in increasing the sensitiveness of autochrome plates about 30 times. The process was also applicable to ordinary plates, increasing their colour sensitiveness as well as their ordinary sensitiveness. The defect of the method was that the treated plates would not keep in usable condition for more than a day at the very longest. Hoping to overcome this difficulty M. Monpillard did not publish the details of his method, but deposited a sealed packet with the French Photographic Society. As he is unable to continue the work, he has now desired the Society to open the packet and disclose the information given therein. The process consisted in adding a small quantity of silver chloride dissolved in dilute ammonia to the mixture of the usual isocyanine and carbocyanine dyes (pinaverdol, pinacyanol, etc.). As soon as the sensitising bath has been used, the liquid that adheres to the plate must be quickly removed with a whirler, and the plate then dried by a rapid current of air.

International Astronomical Union.

THE meeting of the International Astronomical Union at Rome on May 2-10 must be considered an unqualified success. The unique interest of the selected meeting-place was doubtless a useful auxiliary in drawing together so large a number of delegates; upwards of 100 were present, representing England, France, Italy, Spain, Holland, Belgium, Denmark, Norway, Sweden, Poland, Egypt, S. Africa, Australia, New Zealand, Canada, United States, Japan, etc.

The inaugural meeting of the Union at Brussels in July 1919 was mainly occupied with questions of procedure; the way was thereby cleared for more purely astronomical discussions on the present occasion. The main aim underlying these was the co-ordination of various branches of observation and computation, so as to obtain as large an output as possible without waste of energy through unnecessary duplication; there was also consideration of methods of observation and reduction, and of the unification of notation. Much of the credit of the success obtained is due to the presidents of the various committees, who had drawn up careful and thorough programmes, after correspondence with their members; these served as a basis for discussion, and were in most cases endorsed with small changes.

The opening meeting was held in the Campidoglio in the presence of the King of Italy; it was addressed by the Mayor of Rome, the Minister of Public Instruction, the president of the organising committee (Prof. Volterra) and by the presidents of the astronomical and geophysical unions (MM. Baillaud and Lallemand). The subsequent meetings were in the beautiful rooms of the Reale Accademia dei Lincei, Palazzo Corsini. The Union met in full conference at the beginning and end of the meeting; the more important discussions were carried on in separate committees, the conclusions of which were reported to the final meeting of the Union.

A summary of the more important conclusions may be of interest. In the matter of notation the Harvard system of spectra was considerably amplified; the prefixes *c*, *g*, *d* are used to denote super-giants, giants, and dwarfs; *e* to denote the presence of emission lines; *p*, *q* to denote peculiarities tending in the direction of Nova spectra; *s*, *n* denote that the spectral lines are sharp and diffused respectively (*n* was used by Rowland to denote nebulous lines in the solar spectrum); *r* denotes reversal, *i.e.* bright lines with a dark centre; *k* denotes stationary calcium lines.

It is proposed to use Mo, M3, M8 instead of M*a*, M*b*, M*c*, and to drop M*d*, it being suspected that the underlying spectrum in the latter case is not of M type; similarly No and N3 replace N*a* and N*b*. S is used for a new type of red stars, to which R Cygni and R Andromedae belong; Q is used as before for Nova spectra; they are subdivided by the suffices, *a*, *b*, *c*, *u*, *x*, *y*, *z*, in which the absorption spectrum grows progressively weaker, and the bright-line spectrum stronger; in general a star traverses these types in the above order in the weeks or months succeeding the outburst.

Another point of notation decided was that the constellations should be given their Latin names, which has been done in England but not in France. As regards the Carte du Ciel, special votes of thanks were passed to Cardinal Maffi and to the Nizam of Hyderabad for their great assistance in carrying out the astrographic work at the Vatican Observatory and at Hyderabad. Representations were sent to the respective governments concerned, urging the completion of the work of photography and of printing at the observatories of Catania, Melbourne, and Sydney. The progress of work at the other observatories is good or hopeful, though it was much retarded by the war. Prof. Turner reported that the maps of the lunar surface had been completed, and the list of crater-names prepared, but not yet inserted on the maps. M. Lecointe announced that the Uccle Observatory would not continue the distribution of astronomical telegrams after the end of 1922. The offer of M. Strömgren to send them from Copenhagen (as he did for some years after the outbreak of war) was accepted.

The variable star committee met under the chairmanship of Prof. H. Shapley; it is in this section, above all, that co-ordination of work is imperative. It was decided to print several appendices, giving bibliographies of variables, lists of those needing observation, and determining centres of publication for various classes of stars; the Cracow Observatory undertook the preparation of ephemerides of eclipsing variables; attention was also directed to the useful reprints of Father Hagen's charts of the fields of several variables. Regarding the nomenclature of Novae, it was recommended to use the constellation name followed by the year of discovery; the method of giving numbers 1, 2, 3, etc., to the Novae in each constellation leaves a doubt as to which early observations to include; their status as Novae is sometimes doubtful.

It was decided to continue to give the grants in aid of the distribution of wireless time-signals, at least for the next three years. Prof. Sampson, the president of the committee, spoke in support of the great value of these signals both for longitude determinations and for checking the time determinations at different observatories; he discussed these recently, finding that each observatory had frequently a large discordance that remained nearly constant for some time. These discordances were the subject of an interesting debate between the astronomers and geodesists; the latter stated that they did not find these discordances in their field work, and ascribed them to irregularities of refraction due to the walls surrounding the observing room.

The committee on calendar reform reported in favour of continuing the Gregorian calendar, and of omitting one day in each year (two in leap-years) from the weekly reckoning; however, the latter point was not adopted by the general meeting of the Union.

The committee on stellar parallaxes expressed the hope that workers would photograph each parallax field at ten years' interval, in order to determine the proper motions in each element of the comparison stars.

Great praise is due to the Italian astronomers for their excellent arrangements for the meeting, and the help they afforded to the visitors; mention may be made in particular of Prof. Abetti, who showed great skill as an interpreter.

The next meeting was fixed for 1925 (probably in August) at Cambridge, with Prof. W. W. Campbell as president. The Geodetic and Geophysical Union will meet in Madrid in 1924.

The members of the Astronomical Union were received in audience by the Pope on May 10, being individually introduced to him by Prof. Pio Emanuelli, secretary of the Vatican Observatory. The Pope briefly addressed them, expressing the hope that the meeting of so many nations for a common object would tend to the pacification of the world, and that their studies of the marvellous structure of the heavens would lead to increased knowledge of and reverence towards the Creator.

A. C. D. CROMMELIN.

British Science Guild.

MUCH success attended the annual dinner of the British Science Guild, which was held at the Prince's Restaurant, Piccadilly, on May 23, with the president of the Guild, Lord Montagu of Beaulieu, in the chair. After the loyal toasts had been given by him, Sir Arthur Mayo-Robson, in proposing "The British Science Guild," said he was sure that there is a wider and deeper interest among the public in regard to recent scientific work, and this interest would be far greater if only scientific discoverers would put their discoveries into works that were more accessible to the public. In nearly all cases technicalities could be very much modified in description, and it would be a great advantage if some of the wonderful discoveries could be put in plain language. Thinking people of various parts of the Empire are just as anxious to learn of these matters because they see much of the application of science. The Guild would be doing very valuable work if it could establish centres in those distant places. The toast was supported by Commdr. L. C. Bernacchi, who spoke of the appeal which will shortly be launched with the object of raising funds to enable the Guild to carry out its legitimate and laudable aims, the encouragement of research and the application of scientific method to all public affairs.

Lieut.-General Sir Alfred Keogh, proposing "Science and Industry," said it had been the custom to rail at industries as having no appreciation of science, or modern discovery, and of being slow to adapt themselves to new developments. However true this may have been in the past, there is no truth in it now. The leaders of industry are fully alive to the importance of science, and that is due partly to the wonderful work of the Department of Scientific and Industrial Research and the Research Associations which had been formed in connection with the great trades.

Sir Edward Boyle, replying, said that we were faced to-day as never before by political, social, industrial, economic, and ethical questions. We can face them with hopes of success only in the spirit in which men of science have fought disease; that is, if we face them logically, by investigation, by experiment, impartially, thoroughly, accurately; in a word, if we face them scientifically. Prof. Huxley, who was fighting the battles of the Guild thirty and forty years ago, said that science was nothing more than organised common-sense.

The president gave the toast of "The Guests," and referred to the way in which science was solving modern problems. In one direction with which he was associated, the making of roads, we had only just begun to apply the teachings of science. The chemist is just as necessary to-day for making roads, for example, in deciding the proper mixture of bitumen and sand to make the surface or carpet of the road, as he is for making dies, explosives, or medicines. The toast was acknowledged by Principal Ernest Barker, Mr. H. G. Wells, and Mr. F. W. Sanderson.

Mr. H. G. Wells, who was called upon unexpectedly, said that science was to him a thing so great, so all-important, so entirely such salvation as man had before him, that it was with a feeling of irreverence that he found himself talking about it in an unprepared fashion. By science is meant a process of human intellectual energy which is exhaustively and reverently criticised, leading, it is hoped, to action exhaustively criticised before it is exhaustively planned. In that he expressed the whole of his faith, the whole of his belief in human life. An uncharitable person might entertain the view that the Guild had some idea of monopolising science or claiming science for the purposes of the British Empire, but there was something bigger in their minds than that. Science is a great thing which is going to carry human affairs above those levels, and when we think of science and of the Guild, it means that we of the British community hope to contribute our share to the bigger human process, and to play our part to the best of our ability, with no national and imperial aggressiveness, in the huge task of humanity which is involved in the scientific process.

University and Educational Intelligence.

CAMBRIDGE.—Dr. Searle, Peterhouse, has been reappointed University Lecturer in Experimental Physics, Mr. S. Lees, St. John's College, University Lecturer in Thermodynamics, and Mr. F. Lavington, Emmanuel College, Girdlers' University Lecturer in Economics.

The Botanic Garden Syndicate invite the attention of the University to the very critical financial position of the garden. They have received generous gifts to help in restoring the garden to its pre-war efficiency, but unless the income of the garden can be considerably increased drastic steps will have to be taken which must involve a diminution in its educational value.

It is proposed that a site of seven acres belonging to King's and Clare Colleges and lying between West Road and Burrell's Walk should be purchased for the erection in due course of a new library, the present library not being large enough to meet its growing requirements.

LONDON.—The Senate has made the following appointments:—Dr. R. W. Chambers to the Quain Chair of English language and literature, tenable at University College, in succession to Dr. W. P. Ker, resigned.

At the meeting of the Senate on May 24, Dr. R. M. Walmsley took his seat for the first time since his election as Chairman of Convocation in succession to Sir Edward Busk. In this connection a resolution was adopted in the following terms: "That on the occasion of Sir Edward Busk's retirement from the Chairmanship of Convocation the Senate desire to place on record their cordial appreciation of the services which he has rendered to the University during the past thirty years."

Mr. N. B. Jopson has been appointed to the University Readership in Comparative Slavonic Philology, tenable at King's College, and Mr. R. B. Forrester, to the Sir Ernest Cassel Lectureship in Commerce, tenable at the London School of Economics.

A course of four lectures on "Phänomenologische Methode und phänomenologische Philosophie" will be given in German by Prof. Edmund Husserl, professor of philosophy in the University of Freiburg, at University College, on June 6, 8, 9, and 12 at 5.30 P.M. At the Imperial College of Science and Technology (South Kensington, S.W.) Dr. A. F. Holleman, professor of organic chemistry in the University of Amsterdam, will lecture in English on recent investigations on the substitution in the benzene nucleus, on Wednesday, June 7, at 5.15 P.M.

The following lectures will be given by professors of Dutch Universities at the Royal Society of Medicine (1 Wimpole Street, W.1): On Monday, June 12, "Injurious Agents and Growths," by Dr. M. Jansen (of Leiden) at 5 o'clock. On Wednesday, June 21, "The Pathology of Hæmoglobin," by Prof. Dr. A. A. Hijmans van den Bergh (of Utrecht).

Both lectures will be delivered in English. Admission to all the above lectures is free without ticket.

APPLICATIONS for a Mackinnon Research Studentship of the annual value of 300*l.* will be received by the Secretaries of the Royal Society until June 19. The studentship, which is awarded in the first instance for two years with a possible extension, is for the furtherance of natural and physical science, and for original research and investigation in pathology. Particulars and forms of application can be obtained from the Assistant Secretary of the Royal Society, Burlington House, W.1.

APPLICATIONS are invited by the Ministry of Agriculture and Fisheries for a number of research scholarships in agricultural science, each of the annual value of 200*l.* and tenable for three years. Candidates must be honours graduates of a British University with special qualifications in chemistry, botany, zoology, physiology, or economics. The object of the scholarships is to train agricultural research workers, and the work undertaken must be approved by the Ministry. Scholars may be required to spend a part of their time at an approved foreign laboratory or university. Conditions of the award and copies of the form upon which applications must be made are obtainable from the Secretary of the Ministry of Agriculture and Fisheries, Whitehall Place, S.W.1. Nominations for scholarships, which must be signed by a professor or lecturer of a university or college, must be received by July 15.

THE *Chemiker Zeitung* of May 11 reports that Prof. K. Freudenberg is to succeed Prof. Pfeiffer at the Technische Hochschule, Karlsruhe.

IT is announced in *Science* that Miss Kate C. Garrick, daughter of the late Sir James Francis Garrick, for ten years agent-general in London for Queensland, has by her will bequeathed 10,000*l.* to the University of Queensland to found a James Francis Garrick professorship of either law or medicine, as may seem best to the University, in memory of her father.

ON Saturday, May 6, the undergraduates of Aberdeen University concluded a week's "Carnival" on behalf of the local hospitals with a sand-castle competition on the beach and a pageant in the Mitchell Hall. There were 20,000 spectators at the building of the sand castles. More than 3000*l.* was collected in the city and surrounding towns to which artistes were dispatched in the early days of the week.

FURTHER Research Studentships, about four in number, are being offered to university graduates by the Empire Cotton Growing Corporation and the British Cotton Industry Research Association. The studentships are each of the value of 250*l.*, with certain additional allowances, tenable for one year with a possible renewal for a second year. They are intended to provide opportunities for further training in scientific research bearing on plant genetics and physiology, entomology, physics, etc., or in special subjects relating to administration and inspection in tropical agriculture. One studentship is offered for a candidate having special interest in bacteriology. Further particulars and forms of application are obtainable from the Secretary of the Empire Cotton Growing Corporation, Millbank House, Millbank, S.W.1, not later than June 19.

WE learn from *Chemiker Zeitung* of April 22 that Prof. A. Gutbier, Rector of the Technische Hochschule, Stuttgart, has succeeded Ludwig Knorr as professor of chemistry at the University of Jena.

Calendar of Industrial Pioneers.

June 3, 1803. William Reynolds died.—The son of a successful ironmaster at Ketley, Staffordshire, Reynolds invented a method of raising boats from one level to another by inclined planes, with Telford constructed a cast-iron aqueduct at Longden, Shropshire, and in 1799 patented a method of preparing iron for conversion into steel by the use of manganese.

June 3, 1899. John Nixon died.—The pioneer of the steam-coal trade of South Wales, Nixon was born in Durham in 1815 and was trained there as a mining engineer. In 1839 he removed to South Wales and then to France. His observations on the steaming qualities of Welsh coal led to his shipping a cargo to Nantes, and to a contract for the supply of coal to the French Navy, steps which led to the foundation of the great trade in this coal.

June 4, 1907. Sir Charles Mark Palmer died.—The founder of the great shipbuilding and ironworks at Jarrow, Palmer, who was born in South Shields in 1822, was the son of a shipowner. He early became partner in a colliery business, and in 1851 built the first iron steam-collier for carrying coals from Newcastle to London. During the next forty years no fewer than 600 vessels were built at Jarrow.

June 4, 1906. Francis William Webb died.—A prominent locomotive engineer, Webb was an assistant first to Francis Trevithick and then to John Ramsbottom of the London and North-Western Railway, and in 1871 succeeded the latter as chief mechanical engineer, a post he held till 1903. He was a pioneer of the compound locomotive, and in 1881 with the *Experiment* introduced three-cylinder compound engines, and in 1897 with the *Black Prince* introduced the four-cylinder compound engine.

June 6, 1878. Robert Stirling died.—Stirling, who was born in 1790, was for 53 years minister of the parish church of Galston, Ayrshire. Ordained in 1816, the same year he took out his patent for an engine which produced motive power by means of heated air.

June 7, 1884. Richard March Hoe died.—The well-known New York firm of printing-machine makers, Messrs. R. Hoe and Co., was founded by Robert Hoe, an inventor who was born in England in 1784, emigrated to America in 1803, and died in 1833. His son, Richard March Hoe, born in 1812, was the inventor of the high-speed printing press. He devised the means of holding the type on the cylinder, and built machines having ten cylinders and capable of printing 20,000 newspapers per hour. These machines were used in London in 1858. Many improvements were added by Richard Hoe and by his nephew Robert Hoe (1839–1909), who became head of the firm, and it has been said that "to think of 166,000 sixteen-page newspapers printed in an hour, all folded ready for delivery, a feat made possible by the combination of distinct machines, is to think of the name of Hoe."

June 8, 1882. John Scott Russell died.—One of the most eminent naval architects of last century, Russell was born in Glasgow, May 8, 1808. An original investigator, he made experiments on the resistance of water to the motion of floating bodies, discovered the wave of translation, and developed the wave-line system of construction of ships. Removing to London he became secretary to the Society of Arts, and a commissioner of the Great Exhibition of 1851, and established shipbuilding works at Millwall, where Brunel's *Great Eastern* was built. This remarkable vessel, begun in 1854 and completed in 1859, was 680 feet long, 82 feet beam, and of 27,384 tons displacement.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, May 18.—Sir Charles Sherrington, president, in the chair.—T. B. **Wood** and J. W. **Capstick**: The progress of metabolism after food in swine. Using a calorimeter recording electrically the main loss of heat, the resting metabolism of a hog has been recorded at intervals after feeding, varying from a few hours to six days. The excess of the resting metabolism above the basal, at any moment, is independent of temperature, weight, and age of animal. This excess falls off according to the equation $\log y + At = C$, y being the excess, t time since meal, and A and C constants. This equation is identical with Guldberg and Waage's Law of Mass Action, that the rate of decomposition of a substance at any time depends on amount remaining undecomposed. Analysis shows that the excess depends on the pressure in the body of substances resulting from digestion and affecting the rate of metabolism, which are themselves metabolised according to the mass-action law.—J. A. **Gardner** and F. W. **Fox**: The origin and destiny of cholesterol in the animal organism. Pt. XIII.—On the autolysis of liver and spleen. The autolysis of pulped spleen and liver, during periods varying from one day to a month, shows that the cholesterol content remains constant, within the limit of experimental error, and the addition of pure cholalic acid has no effect. Autolytic experiments afford no evidence that these organs are concerned with the synthesis or destruction of cholesterol in the organism.—C. G. **Lamb**: The geometry of insect pairing. Cases of asymmetrical hypopygium found in certain dipterous families, and in other insects would necessarily result if the usual vertical position of pairing was adopted subsequent to a primitive linear position.—G. E. **Briggs**: Experimental researches on vegetable assimilation and respiration. Pt. XV.—The development of photosynthetic activity during germination of different types of seeds. The seedling leaves of Helianthus showed practically full activity immediately after germination, both when light and when temperature were limiting. Other plants showed practically none. In the type showing the lag between germination and development of photosynthetic activity, the seedling possesses a specialised photosynthetic organ separate from the storage organ, while in the other type the same organ serves the dual purpose. Pt. XVI.—The characteristics of subnormal photosynthetic activity resulting from deficiency of nutrient salts. *Phaseolus vulgaris* was grown in a complete culture solution, and in culture solutions devoid of potassium, magnesium, iron, and phosphorus, respectively. The assimilation of leaves from the plants was measured by determining their output of oxygen. Two types of determinations were made: in one the intensity of illumination was so small that light was limiting; in the other, the intensity was increased until assimilation was limited by temperature. Plants grown in normal solution showed greater photosynthetic activity, and in the others the depression was the same when light was limiting as when temperature was limiting. Probably the factor inside the plant involved is the amount of "re-active chloroplast surface." Therefore activity should be sub-normal when carbon dioxide is limiting, a condition for which some evidence exists.

Geological Society, May 10.—Prof. A. C. Seward, president, in the chair.—E. **Garwood** and Miss E. **Goodyear**: The lower Carboniferous succession in the Settle District and along the line of the Craven Faults. Detailed mapping of definite faunal horizons was employed. Two distinct facies can be recognised, the North Country and the South Country types. The whole of the country north of the North Craven Fault belongs to the North Country type. The beds show a deeper water origin than those of corresponding horizons in Westmorland. There is no Bryozoa band, but the Porcellanous Bed which also occurs at that horizon is taken as the base of D_1. The Main Limestone is less fossiliferous than is the case in Wensleydale, while both the *Cyrtina-septosa* band and the Girvanella nodular band are well developed, and constitute admirable horizons for mapping. A second nodular band occurs in the Lower Lonsdalia Bed. The strip of country between the faults belongs, as a whole, to the North Country type, and marks the southern margin of the North-Western Province. The Orionastrœa band forms an important horizon here, and represents the summit of the Hardraw-Scar Limestone round Ingleborough; below it occurs a Bryozoa band. The area is traversed by numerous normal faults trending usually north-westwards and south-eastwards; but, near Ingleton, the beds are repeated on themselves by thrusts. At three places, between the faults, patches of rock belonging to the South Country type occur. The change in the faunas is everywhere accompanied by an abrupt lithological change, which usually takes place along the line of the Middle Craven Fault. There is no evidence that the change was influenced by faulting during Lower Carboniferous times. The "knoll-reef" limestone represents a special type of deposit. The two facies were probably laid down some distance apart, and brought together by thrusting; the patches of rock of the southern type lying between the faults are portions of an overthrust mass from the south which have escaped denudation. The Middle Craven Fault is a normal fault which took place subsequent to the thrusting.—E. J. **Wayland**, and A. M. **Davies**: The Miocene of Ceylon. Arenaceous and calcareous strata of Miocene age are found over an extensive area in the north and north-west of Ceylon, and in a small part of the southern coast, at Minihagalkanda. At the latter place the beds rest upon Archæan rocks. The whole series appears to constitute a cycle of sedimentation, beginning and ending with areno-argillaceous deposits, and consisting mainly of fossiliferous limestones. The fossils consist of Foraminifera, corals, echinoids, and molluscs. The lower horizon of Minihagalkanda is characterised by *Ostrea virleti*, Deshayes, and is dated as Vindobonian (probably Tortonian), while the higher horizon of the northern area contains *Orbiculina malabarica*, Carter, and may possibly be Pontian. The transgression of the sea on the continental area of Southern India and Ceylon is thus contemporaneous with its recession from the Himalayan geosyncline, in accordance with Haug's principle.

Physical Society, May 12.—Dr. Alexander Russell, president, in the chair.—S. O. **Pearson** and H. St. G. **Anson**: Some electrical properties of neon-filled lamps. The lamp is shunted by a condenser and connected in series with a high resistance to a D.C. voltage supply. When cold no current passes through the lamp until the E.M.F. reaches about 171 volts. If the voltage be reduced when the lamp is glowing, current continues to pass until about 140 volts is reached. When, therefore, an E.M.F. of 200 volts is applied, some time elapses while the condenser is charging up to the necessary 171 volts. Then the lamp begins to take current, the current increases, and the voltage across the lamp falls to the limit of 140 volts, when the lamp goes out.

The cycle repeats indefinitely. The arrangement might be used at low frequency for flashing signs, at audio-frequency for telephonic measurements, and at high frequency (up to about 15,000 ~) for radio-signalling.—A. **Griffiths** and W. T. **Heys**: A new apparatus for the measurement of the polarisation capacity of platinum plates in sulphuric acid. Corrections can be made for leakage and self-depolarisation of the cell. It gives results consistent to one or two per cent., and of the same order of magnitude as those obtained by other observers.—Herbert **Chatley**: The molecular forces involved in cohesion. Cohesion may be expressible as a function of molecular masses or of electronic charges. In either case it will also comprise a space-function, and attention may be concentrated on the latter. The r^{-4} law suggested by Sutherland's theory and Van der Waal's rule, would indicate a greater difference in strength than exists in practice between amorphous substances and crystals. The crystal lattice elucidated by Bragg implies a very gradual space-gradient of force as compared with non-crystalline matter. The r^{-4} law is also inconsistent with the Cavendish experiment. Results more consistent with facts are obtained with an r^{-6} law.

Association of Economic Biologists, May 19.—Prof. E. B. Poulton, president, in the chair.—W. **Rushton**: Further contributions to the biology of freshwater fishes. A short account is given of the effects of the effluents from a series of distilleries, a woollen-mill, and from town sewage on the spermatozoa of trout. The life of the sperms is affected, but the eggs can be fertilised in the presence of the effluents. The effects of tree felling on the water supply to a trout hatchery was an increased acidity causing the appearance of a "bloom" on the sides and gills of the young trout, together with a coagulation of the mucus, which resulted in death.—J. H. **Priestley**: The toxic action of illuminating gas on plants. It has been known for many years that the presence of very small traces of unburnt coal gas in the atmosphere may produce a harmful effect upon growing plants under certain conditions. German observers were the first to notice how very sensitive "etiolated" shoots (the shoots of plants grown in continuous darkness) of the pea or potato or many other plants are to the presence of traces of gas. American workers have since extended these observations, and have shown that traces of coal gas in the atmosphere or the fumes from cigarette smoke or smouldering paper might have a very deleterious action upon plants, especially upon such etiolated shoots. Both German and American workers agree that the deleterious effects of coal gas or these other fumes can be traced to the gaseous unsaturated hydrocarbons, such as ethylene, always present in such fumes. If etiolated shoots or roots are placed in an atmosphere contaminated with coal gas or pure ethylene they cease to grow in length and expand in girth instead. These changes in form can be associated with changes in internal structure, notably with the disappearance of the functional primary endodermis. This endodermis forms close behind the growing point in both the etiolated shoot and in the root, and its disappearance seems to account in large measure for the other structural changes and abnormalities of growth seen in plants poisoned by traces of coal gas. The disappearance of the endodermis in the presence of fumes containing unsaturated hydrocarbons can be attributed to the displacement by these substances of the unsaturated fatty acids which normally accumulate upon the walls of the developing endodermis and give this tissue its characteristic properties. The normal leafy stem growing in the light does not develop such an endodermis, and proves relatively insensitive to the presence of these gaseous unsaturated hydrocarbons. These results are of some practical interest in that they suggest diagnostic features by which the occurrence of gas poisoning in horticultural practice may be recognised. The effect is produced by such very low concentrations of ethylene—of the order of one in a million—that although normal British illuminating gas contains very small quantities of ethylene, toxic effects may be produced by traces of the gas too small to be detected by smell. In fact the most delicate test we have for a gas leak possibly consists in the behaviour of etiolated shoots growing in darkness in the contaminated atmosphere. These results may also be of some interest to municipalities interested in the growth of shade trees along urban routes. The gas leaking from the pipes in the soil may be retained around the roots long enough to do damage because of the impermeable nature of the macadam or asphalte of the road surface.

PARIS.

Academy of Sciences, May 8.—M. Emile Bertin in the chair.—The President announced the death of M. René Benoît, correspondent for the section of general physics, and of Sir Patrick Manson, correspondent for the section of medicine and surgery.—A. **Haller** and Mme. **Ramart**: The dehydration of 2-methyl-2-phenyl-1-propanol and of 2·2-dimethyl-3-phenyl-1-propanol. The product varied with the method of dehydration (passage of vapours over infusorial earth at 300°-400° C., action of $SOCl_2$ with or without pyridine). Substituted ethylenes were obtained, the physical and chemical properties of which are given, together with the oxidation products establishing their identity.—C. **Guichard**: The asymptotic lines of surfaces. The study of a particular case.—P. **Montel**: A new theorem of algebra.—J. **Sudria**: A demonstration and the generalisation of Menabrea's theorem.—D. **Riabouchinski**: Some cases of plane movements of fluids round solids with vortices.—Th. **De Donder**: An electromagnetic field comparable with the corresponding gravific field.—L. **Roy**: The electrodynamics of homogeneous isotropic media in repose.—A. **Bigot**: Kaolins, clays, bauxites, etc. Porosity and loss on heating. The loss on ignition of bauxites and kaolins of different origin at temperatures up to 900° C. are shown graphically, and a second diagram shows the changes in porosity of the same materials. M. **Palfray**: Neutral homocamphoric esters and their reduction products.—J. **Froidevaux**: The estimation of ammoniacal nitrogen in nitrogenous organic material, particularly in proteid materials, and their products of hydrolysis. The liquid is treated with a large excess of concentrated caustic soda solution, and the ammonia removed by a purified air stream without heating, with subsequent correction for ammonia formed from the proteid.—A. **Schoep**: Becquerelite, a new radioactive mineral. This is found as a yellow crystalline crust on pitchblende from the Kasolo Mine (Belgian Congo). Its composition is $VO_3 . 2H_2O$.—A. **Gruvel**: The fluvial origin of the bay of Lévrier. The discovery of two species of Potamides proves that the bay of Lévrier is the ancient estuary of a large river.—P. **Thiéry**: The limit of the Bathonian and the Bajocian in Lorraine.—J. B. **Charcot**: The temperatures at different depths in the chasm of Cap Breton. Observations on the variation of the temperature of the sea in the neighbourhood of this gap in the seafloor agree with the views recently put forward by M. Gorceix, but are opposed to the results of P. E.

Dubalen.—Mlle. Yvonne Boisse **de Black**: The Wurmian in the high valleys of the Cère and the Goul (Cantal).—J. **Thoulet**: The distribution of the chalk in deep-sea sediments. A study of the sediments from soundings taken in the region of the Azores and Canaries shows that the depth has little influence on the composition of the deposits arising from Globigerina.—G. **Bertrand**, M. **Freundler**, and Mlle. **Ménager**: The variations in the chemical composition of sea-water and the evaluation of salinity. From determinations of chlorine, calcium, and magnesium in sea-water from the Atlantic and the Mediterranean, the authors conclude that the relative chemical composition of sea-water is not constant.—L. **Mayet**: The Villafranchian fauna of the Chagny Sands (Saône-et-Loire).—J. **Stoklasa**: The influence of selenium on plant evolution, in the presence or absence of radioactivity. Radium emanation exerts a very favourable influence on plant growth, and can (in daylight) neutralise the toxic properties of selenium as dioxide.—F. Lecomte **du Nouy**: The surface equilibrium of serum and of certain colloidal solutions.—P. **Béhague** and J. **Beyne**: Study of the times of tactile psycho-motive reactions in normal man.—L. **Roule**: The ontogenesis of the Scombriform fishes belonging to the family of the Luvarides. The young of this species at first resemble, not their adult parents, but other families (Coryphenides, Lamprides, Stromateides). The metamorphosis is of long duration and the principal changes do not take place in the very young fish, so that the latter might easily be mistaken for individuals of a distinct species.—F. **Ladreyt**: The histogenesis of the basocellular epitheliomas.—H. **Plotz**: Contribution to the study of the culture *in vitro* of the vaccine virus. A rabbit is inoculated with vaccine pulp, and after a suitable interval is bled. Its serum is cultivated *in vitro* in glucose-broth medium. After the fifth passage, the culture fluid inoculated into the skin of the rabbit gives lesions similar to those produced by vaccine pulp. The animals vaccinated in this way are immune to the virus of vaccine pulp.

Official Publications Received.

Agricultural Research Institute, Pusa. Bulletin No. 129: The Preparation of Anti-Rinderpest Serum, using Animals of Moderate Susceptibility as Virus Producers. By W. A. Pool and T. M. Doyle. Part 1: Buffaloes. Pp. 44. (Calcutta: Government Printing Office.) 12 annas.

Annales de l'Observatoire Astronomique de Tokyo. Université Impériale de Tokyo, Collège des Sciences. Tome 5, 5 Fascicule: Recherches sur le mouvement de la comète Wolf. Par M. Kamensky. Pp. ii+65. (Tokyo: Université Impériale.)

Diary of Societies.

FRIDAY, JUNE 2.

DIESEL ENGINE USERS' ASSOCIATION (at Institution of Electrical Engineers).—H. F. P. Purday: Marine Diesel Engines.

SATURDAY, JUNE 3.

ASSOCIATION OF TEACHERS IN TECHNICAL INSTITUTIONS (Annual Conference) (at Polytechnic, Regent Street), at 10.30 A.M.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Hugh Allen: Early Keyboard Music (2).

MONDAY, JUNE 5.

ASSOCIATION OF TEACHERS IN TECHNICAL INSTITUTIONS (Annual Conference) (at Polytechnic, Regent Street), at 10 A.M.—J. Paley Yorke: Presidential Address.
SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.

TUESDAY, JUNE 6.

ASSOCIATION OF TEACHERS IN TECHNICAL INSTITUTIONS (Annual Conference) (at Polytechnic, Regent Street), at 10 A.M.—Viscount Burnham: Address.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Percy Sykes: The Foundation of the Persian Empire.

WEDNESDAY, JUNE 7.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) AND THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF RADIOLOGY AND PHYSIOTHERAPY (at 1 Wimpole Street), at 10 A.M. and 2.30.—Congress of Radiology and Physiotherapy.
ROYAL SOCIETY OF MEDICINE (Surgery Section), at 5.30.—Clayton-Greene, D. Harmer, Dr. E. P. Cumberbatch, and others: Discussion on Diathermy in Surgical Practice.
INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—N. Lea: The Performance of a Radio-Telegraphic Transmitter, with Special Reference to the New Installation at North Foreland.—Prof. C. F. Jenkin: A Dynamic Model of Tuned Electrical Circuits.
SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—Dr. J. C. Thresh: The Action of Natural Waters on Lead.—Dr. H. E. Annett and M. N. Bose: The Estimation of Meconic Acid in Opium.—Dr. A. F. Joseph and F. J. Martin: The Composition of Cows' Milk in the Sudan.—W. Singleton: The Use of the Daylight Lamp in Volumetric and Colorimetric Analysis.
ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

THURSDAY, JUNE 8.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) AND THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF RADIOLOGY AND PHYSIOTHERAPY (at 1 Wimpole Street), at 10 A.M. and 2.30.—Congress of Radiology and Physiotherapy.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Very Rev. Dean Inge: Theocracy (3). The State Invisible.
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 5.—Dr. D. S. Maccoll: What is Architectural Design?
LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—L. J. Mordell: (1) Gauss's Sums and the Law of Quadratic Reciprocity in any Field. (2) The Integer Solutions of the Equation $ey^1 = ax^3 + bx^1 + cx + d$.—J. E. Campbell: The Deduction of the Ground-form of Einstein's Statical Gravitational Field from Gauss's Expression for the Ground-form in Ordinary Two-way Space.—J. L. Burchnall and T. W. Chaundy: Commutative Ordinary Linear Differential Operators.—G. H. Hardy and J. E. Littlewood: Fourier's Series and Power-Series.—Lt.-Col. A. Cunningham: On Pellian Chains.—H. W. Turnbull: On the General Invariant Theory of Quadrics.—J. Vint: Surface Waves on Limited Sheets of Water.—D. K. Picken: The Euclidean Geometry of Angle.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. Gordon Holmes: The Symptoms of Cerebellar Disease and their Interpretation (Croonian Lectures) (1).
OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—Joint Conference between Ophthalmologists and Opticians on Spectacle Construction.
CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Dr. H. H. Dale: Chemical and Physiological Properties (Lecture).
OIL AND COLOUR CHEMISTS' ASSOCIATION.

FRIDAY, JUNE 9.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) AND BRITISH ASSOCIATION FOR THE ADVANCEMENT OF RADIOLOGY AND PHYSIOTHERAPY (at 1 Wimpole Street), at 10.30 A.M. and 2.30.—Congress of Radiology and Physiotherapy.
PHYSICAL SOCIETY OF LONDON, at 3.30.—Visit to the National Physical Laboratory, Teddington.
ROYAL SOCIETY OF ARTS (Dominions and Colonies Section), at 4.30.—Major Sir Humphrey Leggett: Tanganyika Territory.
ROYAL ASTRONOMICAL SOCIETY, at 5.
MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society).
ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Annual General Meeting.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—J. Barcroft: Physiological Effects at High Altitudes in Peru.

SATURDAY, JUNE 10.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) AND THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF RADIOLOGY AND PHYSIOTHERAPY (at 1 Wimpole Street), at 10 A.M. and 2.30.—Congress of Radiology and Physiotherapy.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Hugh Allen: Early Keyboard Music (3).

PUBLIC LECTURES.

(A number in brackets indicates the number of a lecture in a series.)

TUESDAY, JUNE 6.

KING'S COLLEGE, at 5.30.—Dr. D. Subotić: Influence of Geography on the Economic Conditions of Jugo-Slavia (2).
UNIVERSITY COLLEGE, at 5.30.—Prof. E. Husserl: Phänomenologische Methode und phänomenologische Philosophie (1). (In German.)

WEDNESDAY, JUNE 7.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, at 5.15.—Prof. A. F. Holleman: Recent Investigations on the Substitution in the Benzene Nucleus. (In English.)

THURSDAY, JUNE 8.

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 5.—Prof. W. Bulloch: The Historical Development of the Doctrines of Croup and Diphtheria.
UNIVERSITY COLLEGE, at 5.30.—Prof. E. Husserl: Phänomenologische Methode und phänomenologische Philosophie (2). (In German.)

FRIDAY, JUNE 9.

UNIVERSITY COLLEGE, at 5.30.—Prof. E. Husserl: Phänomenologische Methode und phänomenologische Philosophie (3). (In German.)

SATURDAY, JUNE 10, 1922.

Biological Terminology.

THE long-drawn-out discussion on biological terminology which has been a feature of the past year's numbers of NATURE has certainly supplied some food for thought. The state of Denmark may not be so rotten as Sir Archdall Reid believes, but no one who shares his enthusiasm for lucidity will maintain that biological terms are as crisp and unambiguous as could be wished. The reasons for vagueness are not far to seek. The first applies to all the sciences: that concepts change their content from age to age while the words remain the same. This applies to chemistry and physics, and even to mathematics; it must *a fortiori* apply to a young science like biology. Fresh facts demand that some alteration be made in the frames in which they have to be included—terms like 'organism,' 'development,' 'variation,' 'heredity.' The terms must remain, but their content requires continual readjustment. Sometimes, no doubt, new terms are needed, but the invention of good terms is a rare gift.

The second reason for biological vagueness is that biologists are not addicted to philosophy, using the word to mean a criticism of categories. Biologists are plain people dwelling in tents; they are not disciplined in methodology and the art of formulation. To many of them it has not occurred that there is any particular difficulty in terms like 'organism,' 'individual,' 'development,' 'differentiation,' 'evolution.' Some of them use the word 'development' in the forenoon and the word 'evolution' in the afternoon, meaning the same thing both times. Others use the term 'variation' in almost as many different senses as Herbert Spencer gave to the word 'force,' or the older economists gave to the word 'value.'

An outsider, reading Sir Archdall Reid's exposure of biology as 'morass,' 'a tumbling-ground for whimsies,' and so forth, may feel somewhat disturbed. Biologists are accused of playing with undefined terms like 'characters,' 'acquired,' 'inherited,' 'innate,' 'transmitted,' and the impression made on the innocent reader's mind is that biology is in a very unsatisfactory state. But things are not so bad as they seem. A term like 'acquired character' has entered the scientific dictionary as a technical term; it is not happy, but it is not ambiguous; every biologist who knows his business uses it in the same sense; it may be dropped—the sooner the better—but it cannot be re-defined; if we use it at all we must use it as Spencer and Weismann did, meaning a structural change in the body imprinted in the individual lifetime as the direct result of some new peculiarity in functional, nutritional, or environmental nurture, and taking such

grip that it persists after the inducing conditions have ceased to operate. It may be advisable to drop the term 'acquired character' in favour of 'somatic modification,' or the like, but there is not in the mind of the competent biologist any confusion whatsoever in regard to what 'acquired character' means. He uses it as he might use a symbol 'A.C.'

It may be of use to try to state in outline the meaning which biologists attach to the terms they use in describing the facts of variation and heredity. When we compare a thousand descendants of two parents of known pedigree (we are evading the difficult question of 'species'), we may find that they are far from being all alike. They may differ from one another and from the norm of the stock to which they belong. These individual peculiarities can be measured and registered, and they might be called 'observed divergences,' 'observed differences,' 'new departures,' and so forth, so as to avoid any question-begging term. They are changes, at any rate, and many biologists apply to them the general word 'variations.'

When we begin to study the observed differences critically, we find that some of them are directly due to nurtural peculiarities. They are novelties due to novel conditions,—of use and disuse, or of food, or of surroundings. This individual has been imprisoned and that one has been overworked; this individual has been starved and that one overfed; this one has been brought up in a cave and that one exposed to the sun. The resulting differences are somatic modifications or acquired characters. They are exogenous, imprinted from without, what Weismann called 'somatogenic,' what might be called dints in colloquial biology. The goldfish kept three years in darkness loses the rods and cones of the retina; the tropical explorer becomes permanently tanned; the peach-trees taken to Reunion became evergreens, though it took some of them twenty years.

Every character is the *product* of hereditary 'factors' and a certain minimum nurture—food, oxygen, water, and a succession of liberating stimuli; but 'modifications' are lasting changes wrought on the body of the individual as the direct result of some peculiarity in the conditions of life. A modification is more than a response to liberating stimuli; it is an imprint, a dint, a parry to a nurtural thrust. The development of the head will only occur within certain limits—the primary conditions of viability; but the racial peculiarities of the skull are in a different category from deformations imprinted before or after birth. Sir Archdall Reid says this is a distinction without a difference. But we think he is making fun of us.

Of course none of these distinctions is absolutely hard and fast, for we are dealing with the complexity of life. Thus it is not easy to draw a firm line between temporary *adjustments* like sunburning, and lasting *modifications* like tanning. On the other side, there are great differences in the degree in which the developmental expression of hereditary 'factors' demands particular nurtural conditions. Up to a certain point the development of the lung of the embryo chick proceeds without functioning—the gramophone of the inheritance continuing to unwind after the spring has been released. But beyond a certain point the actualisation of the hereditary lung 'factors' will not go *unless the chick breathes*. For a short time an embryo rabbit will go on developing outside the mother; which shows that the environmental dependence is not so narrowly limited as one might think. On the other hand, there are several well-known mutations in the fruit-fly Drosophila which never find expression unless there is some particular external condition, such as humidity. As the next generation shows, the primordium of the character is part of the inheritance, but it remains latent or unexpressed.

Now when we add up all the peculiarities that can be reasonably interpreted as modifications and subtract them from the total of observed differences, we get a remainder—variations as opposed to modifications; or, if the term variations has been already used more widely, *germinal variations* as opposed to Lamarck's "*changements acquis*." They occur among individuals *living under the same nurtural conditions*. They arise from within, endogenously, centrifugally; they are 'blastogenic' in Weismann's phraseology; they are expressions of new permutations and combinations among the germinal 'factors,' 'genes,' or 'determinants'; they may be expressions of changes in the constitution of a 'gene' itself. We know very little as to the origin of these germinal variations *sensu stricto*, but there is no confusion in our concept. Then we may proceed further to distinguish quantitative gametogenic fluctuations from qualitative gametogenic mutations, meaning by the former a little more of this and a little less of that (a longer feather, a higher crest), meaning by the latter a discontinuous or transilient variation, such as a laciniate condition in the Greater Celandine leaves or hornlessness of calves in a horned race. But in the present state of ignorance the categories of variation are necessarily very debatable.

The scheme runs thus :—

$$\text{OBSERVED DIVERGENCES}\begin{cases}\text{GAMETOGENIC VARIATIONS}\begin{cases}\text{FLUCTUATIONS}\\\text{MUTATIONS}\end{cases}\\\text{SOMATIC MODIFICATIONS}\end{cases}$$

What terms are used does not seem urgently important; there has often to be a long struggle for existence among

terms. What is important is that biologists understand one another, and, in spite of Sir Archdall Reid, we protest that they do. One expert may say, "I prefer to use the term fluctuations not for slight intergrading variations, but for certain kinds of modifications"; another may say: "What you diagnose as 'fluctuating *variations*' are really 'fluctuating *modifications*,' though I confess I cannot put my finger on the peculiarity in nurture that induces them." Both may be right; both may be wrong; but there is not in either of them any confusion of thought. Prof. MacBride finds evidence of the transmission of acquired evergreenness in peach-trees; we think that the results may have been due to antenatal infection with certain metabolites, for the seed sojourns for a long time in intimate union with the parent. This is a question of interpretation; there is no confusion of thought in regard to the meaning of 'acquired character.'

In his year of letters Sir Archdall Reid discovered so many mares' nests that we cannot get rid of the suspicion that he has been laughing up his sleeve all the time. Since the scientific study of heredity began, with Darwin let us say, it has been clear that words like 'inherit' and 'transmit' are metaphorical, but has any biologist been misled? Heredity, after all, is but a convenient term for the genetic relation between successive generations,—a relation in which the persistence of a specific organisation is secured through the continuity of the germ-plasm, and yet not so rigidly secured as to shut out the possibility of new germinal variations. Except colloquially, the antithesis is not between heredity and variation, but between complete hereditary resemblance and divergence. The inheritance is all that the living matter of the fertilised egg-cell includes in virtue of its strictly hereditary relation. It would not in the strict sense include either a symbiotic alga or an antagonistic microbe.

The vehicles of the specific organisation are 'factors,' 'genes,' 'determinants,' many of which are certainly located in the chromosomes of the nuclei, but there are also extra-nuclear vehicles, *e.g.* organ-forming substances in the cytoplasm. What the genes precisely are remains uncertain; they are the germinal representatives or initiatives of subsequent differentiations; in a few cases already it seems possible to say that a particular gene, *e.g.* one affecting eye-colour in so-and-so, lies about the middle of the third chromosome! A character in the fully-formed organism is usually the expression of several genes, and the same gene may affect several characters. Every biologist agrees with Sir Archdall Reid that the inheritance is made up of factors for characters, not of the characters themselves, for a character is the *product* of nature and nurture. But just as Darwin sometimes spoke, for short, of an adaptation as the result of selection, when he meant, of course, selection acting on successive crops of heritable variations, so it seems unnecessarily purist to insist always on speaking of hereditary factors rather than of hereditary characters. Gerould has shown that conspicuous blue-green caterpillars (of *Colias philodice*) may arise as mutations in a pure race of inconspicuous grass-green caterpillars, and the offspring of the adults into which two blue-greens develop will breed true. But what is inherited is not the coloration of the blood, for that is due to the xanthophyll and chlorophyll of the food-plant. What is inherited is some subtle gene (a nuclear enzyme perhaps) which acts as a decoloriser or inhibitor of the xanthophyll. Yet would it not be a trifle pedantic to insist that the blue-green character is non-heritable.

Whether the specific organisation which persists in the germ-cell lineage can be added to in a definite way by nurtural changes or modifications wrought in the body of the parent, remains a question for legitimate discussion (see, for instance, Mr. Cunningham's interesting "Hormones and Heredity"), but it is not playing the game to say that "there is absolutely no meaning in the neo-Darwinian statement that acquired characters are not transmissible." Some biologists find convincing evidence that a novel somatic modification can affect the germinal organisation in a manner so specific that the offspring show some representation of the acquired character. Others remain unconvinced by any of the evidence that has been as yet adduced. What is wanted is not a rumpus about terminology, but more facts, and more critical interpretation.

Sir Archdall Reid complains that biologists are thirled to a particular classification of characters into 'innate' and 'acquired,' whereas they ought to take a leaf from the physiologist's book. But this is simply another of the windmills at which the Quixotic knight tilts. When thinking along a particular line biologists must distinguish characters as expressions of an intactly persistent germinal organisation, or as expressions of germinal rearrangements—shufflings of the factorial cards, or as dints directly due to peculiarities in nurture, and this does not exhaust the classification *sub specie hereditatis*. But at another time, the biologist is just as open as any physiologist to classifications of characters from other points of view. Are they generic, specific, or varietal; are they adaptive or non-adaptive; are they the outcome of natural selection, or of sexual selection, or of neither; are they exhibited at birth or do they appear in the course of later development (like the curlew's bill); are they activated by hormones or by more general constitutional changes; are they progressive or involutionary, do they illustrate differentiation or de-differentiation? There is no

restricted outlook in the biologist's classification of characters.

Sir Archdall Reid expostulates with biologists for writing down to the 'nature' account what should be put to the 'nurture' account, but the biologists agree with him in *not* keeping two accounts. The mistake of making an antithesis between 'nature' and 'nurture'—two components of one resultant—is not one to which a biologist can plead guilty. But the biologist understands the difference between hereditary nature realising itself in its normal nurture, and hereditary nature being indented by novel peculiarities. It need not be a 'glaring' nurtural peculiarity, as Sir Archdall Reid says,—a minimal change, *e.g.* in salinity, may serve. It must not be supposed, however, that it is easy to distinguish, especially in mammals and seed-plants, between what are antenatal modifications and what are normal expressions of the inheritance. Much is congenital that is not hereditary. If we only knew the wan newt Proteus in the dark waters of the Dalmatian caves, we should surely conclude that the power of producing pigment was not in its inheritance. Yet we should be wrong. The power of producing pigment has not been lost; it expresses itself whenever the Proteus is exposed to the liberating stimulus of light. Similarly, as to various 'specific characters' of animals, *e.g.* parasites, which we know only from one environment, it may be that some of them are purely modificational, like the green of the Colias caterpillars, and imprinted on each successive generation. Further knowledge may show that many characters which we now regard as 'innate' are only 'imprints' on an innate susceptibility or receptivity. But our inability to say 'yea' or 'nay' in regard to such questions is due to our ignorance, not to any confusion of thought.

No doubt Sir Archdall Reid has made many true statements, *e.g.* that, to begin with, the organism and the inheritance are one and the same; that the inheritance consists of potentialities or factors, not of characters; that a specific character is always the product of 'nature' and 'nurture,' which are complementary, not antithetic; that it is not always easy in practice to distinguish the hereditarily inborn from an antenatal modification; that functioning often counts for much in development. But with these statements all competent biologists are in agreement. To a large extent Sir Archdall Reid has indulged in bogey-hunting and in the pastime of re-editing the scientific dictionary and then importing fallacies into biological argument. To accuse biologists of not dealing with realities is as absurd as indicating that Lamarck's first law is not sense. When a man pulls his bow so tightly as all that, he hits nothing.

Elements and Isotopes.

Isotopes. By Dr. F. W. Aston. Pp. viii+152. (London: E. Arnold and Co., 1922.) 9*s.* net.

DR. ASTON'S book on "Isotopes" is very far from being a mere reprint of his published papers; it constitutes a masterly review of all the aspects of the subject with which he deals. As a result, those who are already familiar with the principal papers which have appeared in the *Philosophical Magazine* will find in the book much that is both interesting and instructive. Thus, the author's account of Dempster's alternative form of the mass-spectograph is particularly interesting; and Dr. Aston has rendered a real service to readers who are not specialists by bringing together in one volume all the methods and results of work on isotopes. His summary of the investigations which have been carried out on radioactive isotopes is particularly concise and readable.

The discovery of isotopes, and particularly of isotopes which are not radioactive, has brought into prominence the necessity for considering afresh the definition of an element. In practice two methods have been adopted. In the radioactive series each isotope has been regarded as a separate element, and has been given a separate name and a separate symbol; this practice has arisen naturally in view of the fact that the isotopes, although having the same atomic number, differ not only in their atomic weight, but also in the source from which they are prepared, and in their stability as measured for instance by the half-life period. On the other hand, it is equally in accordance with traditional methods that chlorine, which has been described as an element ever since the appearance of Davy's celebrated Memoir in 1810, should still be treated as an element in spite of the fact that it is now known to contain two isotopes, the atoms of which differ from one another by two units of atomic weight. This alternative view is supported by Dr. Aston, who recommends that all atoms having the same atomic number should be regarded as isotopes of one element, the number of elements being thus limited to 92. Having regard to the fact that inactive isotopes (with the exception of lead) occur in nature in constant proportions, and that the alteration of these proportions is a matter of very great difficulty, it is unlikely that any complications would arise amongst practical chemists if chlorine and bromine were still to be described as elements instead of as mixtures of elements. It is, however, clear that the two alternative usages which have been described above cannot both persist, and that we must either adopt some common symbol and name for each group of radioactive isotopes, *e.g.* for the three radioactive emanations, or adopt some

distinguishing symbol and name for each of the constituent isotopes of chlorine or bromine, *e.g.* as Dr. Aston has suggested, Cl^{35}, Cl^{37}, Br^{79}, Br^{81}, etc.

This subject was discussed at the recent meeting of the Solvay Institute in Brussels, and the latter alternative appeared to find favour among the majority of the chemists who were present. In this connexion it is of interest to notice that the last occasion on which it became necessary to reconsider the traditional definition of an element arose from the promulgation of Dalton's atomic theory. In his "New System of Chemical Philosophy" (Part I., p. 143) published in 1808, Dalton puts forward the conclusion that "the ultimate particles of all homogeneous bodies are perfectly alike in weight, figure, etc." If this statement be applied to the nucleus atom of Rutherford, it would appear that the atoms of a homogeneous element must be alike both in weight and in the configuration of the protons and electrons of which the atom is composed. Modern investigations have shown that it is possible to find, on one hand, isotopes composed of atoms which possess a like configuration of the planetary electrons in the outer domain of the atoms, but which differ in the weight of the nucleus; on the other hand, isobares are known (*e.g.* Ne^{40} and Ca^{40}) the atoms of which are alike in weight but differ in configuration. It is of course possible that, in the future, atoms may be discovered which are alike both in weight and in the configuration of their planetary electrons, but differ in their radioactive properties as the result of a different arrangement of the protons and electrons in the nucleus, giving rise to a sort of nuclear isomerism. One such case has been suspected amongst radioactive elements; but Prof. Piccard, of Brussels, has suggested that this assumption need not be made if the actinium series of radioactive bodies be assumed to have its origin in an isotope of uranium, instead of in the element which gives rise to the radium series.

On this hypothesis *odd* atomic weights may be assigned to the radio-elements of the actinium series, while retaining *even* atomic weights for those of the radium and thorium series; under these conditions isotopic members of the actinium and radium series would always differ in atomic weight and the occurrence of isobaric isotopes would be impossible. Prof. Piccard states that this conclusion is supported by recent measurements made to test the application to actinium of the Geiger-Nuttall relationship between the penetrating power of the rays and the life of the atoms emitting them. There is therefore at the present time no valid objection in regarding as the criterion of a homogeneous element the fact that its atoms must be alike both in "weight" and in "figure" (as indicated by identical atomic weights and atomic numbers) and using this as a basis in constructing a working definition of the element.

(8) *Plane Geometry for Schools.* By T. A. Beckett and F. E. Robinson. Part 1. Pp. viii + 239 + v. (London: Rivingtons, 1921.) 5*s.*

(9) *Wightman's Secondary School Mathematical Tables.* Edited by F. Sandon. Pp. 96. (London: Wightman and Co., Ltd., 1921.) 6*d.*

(1) THE fact that a third edition has been issued of Prof. Filon's book on projective geometry is a sufficient indication of its usefulness and merit. There is little to record as regards changes or innovations. One would only like to say that while from chapter 2 onwards the book reads fairly plainly, the first chapter is not at all easy reading. Why need the student be frightened off by such an introduction to a subject full of fascination? If a further edition is called for, perhaps the author could see his way to simplify this chapter and improving the illustrations so as to make it more palatable.

(2) A text-book should avoid two extremes: the tendency, on one hand, to include all possible cases that are likely to arise, and all kinds of questions that an examiner is likely to set; and the danger, on the other hand, of presenting the subject-matter of the book in the form of an almost "bald and uncon-

vincing narrative." Prof. Jessop's "Elementary Analysis" is so short that on occasion it seems to err in the direction of the second extreme. Yet it is a very clear and useful account of what the average student needs to know if he is to benefit by further work, where the calculus and the methods of analytical geometry are required. University courses continue to become more and more inclusive, and many students will be grateful to the author for the brief presentation he offers them. The straight line and circle are discussed in about fifty pages, differential and integral calculus occupy about a hundred, and about twenty pages are devoted to the general equation of the second degree and the properties of the ellipse, parabola, and hyperbola. The last chapter is almost tabloid in character.

(3) This, like the other publications of the University Tutorial Press, seems to be just the book required for "learning up" for an examination. Nothing, apparently, is left to chance, and the student who has mastered its contents should be able to defy any examiner to do his worst. On reading this book one feels inclined to exclaim: Did I know all this when I passed the matriculation examination? For a class text-book a shorter book with more emphasis on principles and less on the examination spectre would be preferable: but for private students—and they are more numerous than many suppose—this book has its obvious advantages. In the second edition chapters have been added on indices and logarithms.

(4) and (5) Elementary mathematics is gradually being released from the burden of manipulative skill and the bogey of the examiner. Students are no longer expected to do jig-saw puzzles with mosaics of simple, square, and double brackets, with pluses and minuses peppered about like the charges in the modern chemist's atom. This release is well symbolised in Messrs. Durell and Arnold's two books on algebra, written for American schools. Each book represents a year's course, developed with skill and knowledge of pedagogical methods. In the first book each chapter is divided into two parts, the first for the beginner in his first half-year, the second for revision during the second half-year. It is doubtful, however, whether revision by complete repetition is an ideal educational process. The second book is in two parts, the second being "a reservoir of extra work for bright pupils." The complete course is very suitable for the standard of matriculation.

(6) Messrs. Durell and Arnold's "Geometry" contains a full and competent account of all the pure geometry that is required by pupils of higher schools. The sequence is reasonable, and the treatment is practical although the book is essentially a course on formal geometry.

The subject-matter comprises the usual plane geometry and a rather extensive course on solid geometry. The sphere is dealt with in some detail, and an interesting feature of the book is the brief account of the properties of spherical triangles as regards congruence and area. This is a very desirable innovation that English books might copy with advantage. Spherical figures are of importance in many branches of knowledge and the student must somehow pick up a little knowledge about them: but, like hydrostatics, spherical trigonometry is a step-child of the modern mathematical teacher.

As the authors use algebraic symbols, it would have been an advantage to introduce numerical trigonometrical methods. The historical sketches are rather dull.

(7) Books on practical geometry usually give constructions for a number of geometrical exercises with little justification, if any. Books on formal geometry aim at giving a systematic and logical course on the subject: occasionally a lapse into real life takes place, but the main object is to build up a structure of reasoning based on a few fundamental notions and postulates. Where the theoretical and practical are combined, one usually has the two more or less dissociated. Mr. Foster's idea is to combine the advantages of both the practical and the formal by working them into an organic whole; he tries to inculcate the geometry of the class-room by means of the observation of outdoor and home life. He has achieved considerable success. The separate formal propositions are reduced to a very small number—and this is an advantage. In the two parts already issued the ordinary plane geometry is covered, up to and including proportionality and similar figures. A third part is promised on solid geometry.

(8) Like Mr. Foster, Messrs. Beckett and Robinson make it their aim to combine deductive with practical geometry. They commence with a number of practical constructions without proofs, even such complicated problems as the drawing of common tangents to two unequal circles. The student is then introduced to notions of area and to solid figures, thus completing the preliminary section. Section I. gives the formal geometry of triangles and parallelograms, with exercises from life, mechanics, and physics. In Section II. are given the properties of circles in formal order, while Section III. deals with areas and Pythagoras's theorem. Cartesian co-ordinates are introduced, contours explained, and a brief course on numerical trigonometry completes the first part. It will be interesting to see the second part. Pythagoras's theorem is too late in the book: the student usually feels quite excited about this theorem, and the sooner he gets excited about

geometry, the better. The gradient is too steep in the trigonometrical portion.

(9) Why does Mr. Sandon use the title "Mathematical Tables"? In reality the booklet seems to be intended as a pocket cyclopædia of much, if not all, knowledge. In 96 small pages we get treatises on arithmetic, algebra, mechanics, calculus—gamma functions are also included—astronomy, insurance, geology, philology, chemistry, earthquakes, the Morse code, the size of wall-paper, ship watches and bells, and Suffolk and Essex measures of butter and cheese, to name only a selection. The book may be useful, but the mathematical portions are hopelessly marred by misprints. S. BRODETSKY.

(1) THE following are the first and the last statements in M. Franck's "loi unique." "Tout volume est composée d'une somme de positif qui est son potentiel et de négatif qui est sa masse. . . . Ces variations de potentiel dans l'éther sont elles-mêmes déterminés directement ou indirectement par l'Esprit." This law "nous supposons capable de tout expliquer"—everything, from the origin of the universe, through Boyle's law, to the constitution of electricity. Such books are the despair of the reviewer. If they are frankly denounced as nonsense, a cry is raised about an obscurantist hierarchy impervious to all new ideas; while a careful analysis of them with a view of discovering whether anything valuable is concealed in the tangled mass of verbiage requires an enormous expenditure of time and labour. We announce therefore that we have not read M. Franck's book, and do not intend to read any book which aims at subverting the foundations of physics unless the author tells us, in terms of its language and concepts, exactly in what respect he finds its conclusions unsatisfactory.

(2) At the other extreme in this miscellany is Dr. Pringsheim's monograph. It is a summary of all important work on phosphorescence and fluorescence between 1908 (the date of the summary in Kayser's Spectroscopy) and March 1921, the experiments being interpreted so far as possible according to Lenard's theory modified and expanded in accordance with that of Bohr. The author's name is a sufficient guarantee of excellence, and it is unnecessary to say more than that the work is worthy of his reputation and of the traditions of German book-production. The book has a special and melancholy interest in that it is the product of the author's internment for five years in Australia, whither he had gone to attend the British Association meeting as a guest of the Australian Government. He is naturally bitter about his treatment, and every one must agree that the incident was exceptionally unfortunate; but alas! war is a succession of unfortunate incidents.

(3) Intermediate between these extremes is M. Pacotte's volume, which is "un essai historique, critique et méthodologique" on the new physics. M. Borel in his preface suggests that nobody has the right to criticise an attempt to compress so much matter within 200 pages who is not prepared to perform the task better himself; and we accept his suggestion in so far as we shall make no attempt to discuss whether, in his capacity as historian, M. Pacotte has always traced the true line of development. But criticism and "methodology" imply a point of view, and it is open to any one to suggest that the point of view is mistaken, without falling under M. Borel's ban; for if the point of view is wrong the book is not worth writing. We have no intention of declaring categorically that it is wrong, for science may be viewed from many standpoints, all of which are equally legitimate. But we think it right to indicate that M. Pacotte's standpoint is not that of the average physicist, nor yet that of the average philosopher; both of them will experience some difficulty in understanding what exactly is the task that M. Pacotte is trying to perform. His standpoint is perhaps more nearly that of the mathematician; but if the book is addressed to mathematicians it is surely a defect

and not a merit that it should be wholly free from mathematical symbolism. However, it is clear that M. Pacotte has read and thought deeply, and if we have to confess that the results of his labours are not very helpful to us, we are most ready to admit that they may be very helpful to others.

(4) Prof. Petrovitch here pursues the suggestive train of thought which he has started in earlier works. He begins with the familiar observation that physical metaphors are used in connection with the most diverse events; thus we speak of the *cooling* of enthusiasm or the *oscillation* of public opinion. Such metaphors indicate that the most diverse phenomena follow tendencies (*allures*) characterisic of mechanics. He seeks accordingly to classify these tendencies into a few well-marked groups and to place all phenomena of all kinds whatsoever within these groups according to the nature of their tendencies. These ideas (of which the briefest outline must suffice here) lead naturally to a scrutiny of the whole range of knowledge; M. Petrovitch's knowledge is wide and, so far as we can test it, accurate; yet he carries it easily. Accordingly his book will appeal to many who are not immediately interested in his epistemological theses.

We are inclined to think, however, that he overrates the importance of the resemblances he studies. Thus he maintains that when he has analysed any phenomenon according to its tendencies and displayed its mechanical analogies, he has explained the phenomenon in the sense used by Kelvin when he said that to explain a phenomenon was to construct a mechanical model of it. Such a doctrine we think might lead to the most dangerous fallacies if applied to psychology and politics; and though M. Petrovitch, confining himself to analysis and not to construction, seems always to stop short of the precipice, he approaches it very nearly and might well lead shallow thinkers over it.

(5) Prof. Lenard has republished in pamphlet form an article which appeared in Stark's "Jahrbuch." It is one more attempt to avoid the principle of relativity and quantum theory, and seems, as usual, to forget that it is impossible to avoid them entirely, because, since they are formal theories in accord with experiment, any other physical theory so in accord must be formally in accord with them. The basic idea of Prof. Lenard's theory is that every body has its private ether, disturbances in a private ether being transferred in some way (undefined) to a primary ether (Uräther) for transmission to a great distance. To those so attached to ethers that the idea is attractive of an infinite number of coincident ethers all moving at any point with different velocities, the idea will probably appeal. But we confess that we see no need for the Uräther; so far as we can see, private ethers would suffice, together with the assumption that each observer can only perceive disturbances set up in his private ether. (Cf. *Phil. Mag.* 19. 189. 1910.)

(6) Prof. Planck publishes here a collection of his semi-popular lectures and essays, partly on radiation and quantum theory, partly on scientific principles. All that he says here will, of course, be familiar already to serious students, while for the general reader books in a foreign tongue are seldom useful. No comment therefore seems necessary; to praise Prof. Planck's work would be impertinent.

(7) Finally, we come to M. Villey's very interesting volume, of which the first part only is published as yet. Its intention is "A ceux qui possèdent déjà les connaissances normalement enseignées dans les traités de physique élémentaire, exposer les mêmes matières sous une forme assez renouvelée pour stimuler leur curiosité et élargir leurs points de vue" and "A ceux qui veulent acquérir ces connaissances en mettant à profit leur loisir, les présenter non sous l'aspect du manuel pédagogique, mais sous une forme plus attrayante et de lecture plus facile." It is the second object which appeals more directly to us and, we think, to the author. It is impossible for a professional physicist to decide definitely how far the aim has been achieved; we must "try it on the dog"; but we are certain that if the author has failed, his task is impossible and that the fault lies not with him but with the audience he is addressing. The book is a model of that simple, lucid, and logical exposition of which the French language—or at least the French people—alone seems capable. Every one, however deeply versed in physics, will find in it something to stimulate his interest and imagination. M. Villey deserves the thanks of all who desire a wider diffusion of scientific knowledge; we hope that an English translation will soon appear—if only somebody can be found with the courage and ability to undertake it.

N. R. C.

Strasburger's Text-book of Botany.

Strasburger's Text-book of Botany. Rewritten by Dr. H. Fitting, Dr. L. Jost, Dr. H. Schenck, Dr. G. Karsten. Fifth English Edition Revised with the Fourteenth German Edition by Prof. W. H. Lang. Pp. xi + 799. (London: Macmillan and Co., Ltd., 1921.) 31*s*. 6*d*. net.

THE last English edition of this well-known text-book was published in 1912, and the appearance of the present volume will be welcomed by the large number of students and teachers who are already familiar with its many excellent features. This edition appears under a new title, as "Strasburger's Text-

book of Botany," to commemorate the original founder of the work. The general plan of the book remains the same. The first part, entitled "General Botany," includes morphology and physiology; the second part, "Special Botany," is also in two divisions, the first dealing with Thallophyta, Bryophyta, and Pteridophyta, and the second with the Spermatophyta.

The division on morphology, which is contributed by Prof. Fitting, has been entirely rearranged and largely rewritten. It now begins with a consideration of the cell, tissues and tissue systems, and then under the heading of "Organography" deals with the external form and internal structure of the members of the plant. This arrangement permits of a logical development of the subject, in which some consideration is given to form in relation to function. It is clear, however, that the subjects included in this divison cannot be adequately treated in the 206 pages devoted to it. Such subjects, for example, as leaf fall, structure of the hypocotyl, and the phylogeny of the vascular system, receive very scanty treatment.

In a new section six pages are devoted to the theory of descent and the origin of new species. It is doubtful whether such a condensed account of this subject will be of value to the student even for examination purposes. It is true that, as in other sections of the book, there are references to the more important publications on this subject, but since both here and in the sub-section of physiology dealing with heredity and variability the references are almost exclusively to German authors, these will be of limited use to the English student.

The section on physiology, by Prof. Jost, is on the same general lines as that in the fourth edition. It has, however, been very carefully revised and brought up to date, and provides an excellent survey of the subject.

In the Cryptogamic section, for which Prof. Schenck is responsible, the most recent additions to the subject have been brought under review. Among the Thallophytes, alternation of generations is described and figured in the Laminariaceæ, and Kniep's work on the Hymenomycetes is included. The treatment of the vascular cryptogams has been much improved by the insertion of the more important fossil forms in their natural positions among the existing families.

The work as a whole presents a comprehensive and accurate account of the subject. Its main defect is that, in including so much within the limits of a single volume, the treatment of the various sections has suffered from undue compression. The book was written for German students and it cannot fully satisfy the requirements of English teachers, since it does not give prominence to those aspects of the subject with which the English School of botanists has been identified. Nevertheless, it has already established itself as a standard text-book, and in its present revised form and at its extremely moderate price it will meet the needs of many different types of student.

R. J. T.

German Monographs on Biochemistry.

Die Biochemie in Einzeldarstellungen. Herausgegeben von Dr. A. Kanitz.

(1) *Temperatur und Lebensvorgänge.* Von Dr. A. Kanitz. Pp. x+175. 54 marks.

(2) *Über künstliche Ernährung und Vitamine.* Von Prof. Dr. F. Röhmann. Pp. vi+150+2 plates. 42 marks.

(3) *Über partielle Eiweisshydrolyse.* Von Prof. Dr. M. Siegfried. Pp. iv+64. 15 marks.

(4) *Die Einwirkung von Mikroorganismen auf die Eiweisskörper.* Von Dr. P. Hirsch. Pp. x+256. 63 marks.

(Berlin: Gebrüder Borntraeger, 1915–1918.)

THE present may be emphatically termed the period of Monographs of Science. The vast accumulation of facts has long passed the bounds prescribed by the general treatises on physics or chemistry, in which it was formerly possible to find a readable and critical treatment of the subject as a whole. These were succeeded by encyclopædic dictionaries, of the type of Beilstein, which, however useful and indeed invaluable for reference, make no claim to be readable or even critical. In all branches of science, however, the demand is insistent for a comparatively brief and comprehensive account of the present state of knowledge, and it is to meet this that the various series of sectional monographs have sprung up. Among the first of these were the admirable monographs on biochemistry edited by Hopkins and Plimmer from 1908 onwards, and in the series now under review we have the German equivalent of these. Originated as late as 1915, comparatively few volumes have as yet been issued, but the promised list of publications indicates, both by the subjects proposed and the distinction of the authors, that they will form a valuable addition to the biochemist's bookshelf.

(1) The effect of temperature on life processes is here discussed in great detail. After a general introduction in which the physical chemistry of the subject is considered the characteristic optimum effect produced in living organisms is fully analysed. A special part follows in which a summary of the literature is made and the data are incorporated in tables, each class of phenomenon, such as the heart-beat, the action of

poisons, the duration of life, etc., being separately discussed. This provides a very valuable compendium of the existing information on the subject. Among the most remarkable results recorded are the enormous values of the temperature coefficient ($Q_{10}=1000-4000$) in many cases of the duration of life, especially among invertebrates. In this connection the suggestive fact must be borne in mind that high values of Q_{10} are also characteristic of the denaturation of proteins and the inactivation of enzymes. These high values are the more remarkable as in the majority of cases physiological phenomena fall into line with ordinary chemical reactions, the rate of which is increased 2 or 3 times by a temperature rise of 10° C., although in many cases the coefficient falls with increasing temperature.

(2) Criticism, especially of the fundamental propositions enunciated in a new and rapidly expanding branch of knowledge, is useful because it prompts the investigator to re-examine the experimental foundations on which he has based his conclusions. In this way Dr. Röhmann's work has doubtless done good service, but the theses which he maintains, that accessory food factors or vitamins have no existence in fact and that "deficiency" diseases such as beriberi and scurvy are due to prolonged and one-sided feeding with "imperfect" proteins, can no longer be seriously maintained. The author's experimental material has already been very carefully analysed and criticised by Osborne and Mendel, who have pointed out in what directions the "purified" diets of Röhmann fell short of the standard which is now known to be required.

Since the date of publication of this book (1916) overwhelming evidence has been produced—largely in this country and America—that Hopkins was fully justified in his original conception of accessory food factors which cannot be synthesised by the animal but are necessary for the proper utilisation of its diet, however complete this may be in the fat, carbohydrate, protein and salts which form its main constituents. Röhmann has turned his face back towards the ideas of the older physiologists and his book remains as a monument beside the path by which the newer doctrine has been reached.

(3) The hydrolysis of proteins by enzymes is a highly complex process, the exact course of which is by no means fully understood. In the present work a full account is given only of the later stages of this decomposition, commencing with the peptones and proceeding downwards through the kyrines to the peptides. The term peptone is often used vaguely to designate various mixtures of the hydrolysis products of protein, often including the albumoses. We are here given an excellent account of the work, largely due to the author, by which the peptones, in the narrower sense, have been isolated from the products not precipitated by ammonium sulphate, and have been characterised by their chemical and physical properties. Their composition varies with their origin but is always relatively simple, although the author hints at the existence of modes of union between their constituents other than the characteristic peptide linkings to which so much importance has been attached in the structure of the proteins.

(4) The physiological importance of many of the bases formed by the action of bacteria on the amino-acids has made them of great interest to the biochemist. English readers have already at hand, in Prof. Barger's monograph on "The Simpler Natural Bases," a work which includes a great part of the matter dealt with by Dr. Hirsch. In the present volume the subject is approached from the point of view of bacterial action and a full account of the products which have been recognised is given. In addition to descriptive matter, practical methods are also included and a considerable amount of attention is given to the physiological properties of the substances concerned. Interesting sections treat of the pathological effects of bacterial products derived from the proteins and of their therapeutic application.

The author also includes a short but suggestive chapter on the relation between these products and various substances of a basic character which occur in animal and vegetable organisms. There is little doubt that many of the latter have been formed from amino-acids by reactions similar to those produced by micro-organisms, if not actually by their active intervention. A copious bibliography is appended to the work.

ARTHUR HARDEN.

Our Bookshelf.

Alumni Cantabrigienses: A Biographical List of all known Students, Graduates, and Holders of Office at the University of Cambridge, from the Earliest Times to 1900. By Dr. J. Venn and J. A. Venn. Part I., *From the Earliest Times to 1751.* Vol. 1, *Abbas–Cutts.* Pp. xxviii + 437. (Cambridge: At the University Press, 1922.) 150*s.* net.

THE President of Gonville and Caius College and his son have undertaken an immense task in the preparation of the volumes, the first of which is under notice. Dr. Venn has by previous work on the archives of his own College prepared himself for this investigation, and it is as much due to him as to the wise rules of Dr. Caius that the Caius records of past members can be described as "much the best of the series." There are 76,000 names dealt with up to the date 1751 covered by Part I., and details have been gathered together from many sources. For instance, John Ward of

Cambridge is shown by an Institution Book to have been appointed a rector in 1673; a visitation of 1677 states that he was ordained priest at Norwich in 1672; the Bishop's Register there states that this ordinand was B.A. of Jesus College; by this he can be safely identified, and the Jesus books give his parentage and birthplace.

Naturally not many details can be given even when available of most of the persons named in the book. The great majority entered the Church; and the Reformation, the Commonwealth, and the Restoration figure largely in the doings of the Cambridge graduates. But other professions are represented, such as physicians and lawyers, and more rarely statesmen and diplomats. Occasionally careers ended in the stake, the block, or in simple outlawry. Amongst names in the present volume that will interest men of science are William Croone, in memory of whom was founded the Croonian lecture; Isaac Barrow, "famous as a mathematician, as Greek and Latin scholar, and above all as a theologian"; Peter Barwicke, Censor of the R.C.P., one of the few doctors who worked through the Plague of London; Licius Bomelius, physician, astrologer, and magician to the Czar, who died in prison; and Henry Cavendish, chemist, physicist, and mathematician, who left a fortune of more than a million. It is greatly to be hoped that Part I. of this work will receive sufficient support to enable Part II. (1752–1900) to be published.

Catalogue of 1068 "Intermediate" Stars situated between 51° and 65° South Declination for the Equinox 1900: From Observations made at the Sydney Observatory, New South Wales, Australia, during the Years 1918–1919, under the Direction of Prof. W. Ernest Cooke. Pp. vii+29. (Sydney: W. A. Gullick, 1921.)

SOMEWHAT novel lines have been adopted in this catalogue. Prof. W. E. Cooke has endeavoured to follow literally the resolutions of the Paris Astrographic Congress of 1909, which divided the stars to be observed into three classes—Fundamental, Intermediate, and Reference—the second class being deduced from the first by differential methods, and in turn serving as standards for the third class, which are to be used to give co-ordinates on the Astrographic Plates. The position of the Fundamental stars in the zone were taken from the Cape Catalogue, 1900, using the proper motions given there. The new Catalogue reproduces their assumed places with mean discordances of $0{\cdot}001^s$ and $0{\cdot}02''$. The probable error of a catalogued position is found to be $\pm 0{\cdot}006^s \sec \delta$, and $\pm 0{\cdot}13''$.

Collimation errors and errors of division are determined in the ordinary way, but all other corrections, including the instrumental ones and those due to clock error, precession, nutation, and aberration, are applied by differential formulæ described in Mon. Not. R.A.S., vol. 79, No. 1. It is claimed that this method facilitates the correction of the catalogue places for any changes in the adopted places of the Fundamental stars. The pivot errors of the circle are given, but have not been applied, as the method of reduction should eliminate them. The transits were observed by the travelling-wire method, except for some faint stars which were observed over fixed wires. A constant correction was applied to these to reduce them to the other system. A. C. D. C.

The Serbian Epidemics of Typhus and Relapsing Fever in 1915: Their Origin, Course, and Preventive Measures employed for their Arrest. (An Ætiological and Preventive Study based on Records of British Military Sanitary Mission to Serbia, 1915.) By Col. William Hunter. (Reprinted from the Proceedings of the Royal Society of Medicine, 1919, vol. xiii.) (Section of Epidemiology and State Medicine.) Pp. 29-158. (London: John Bale, Sons, and Danielsson, Ltd., 1920.) 7*s.* 6*d.* net.

IN this account of the Serbian epidemics of typhus and relapsing fever in 1915, Col. William Hunter makes a very interesting and valuable contribution to the medical literature of the war.

The R.A.M.C. Mission arrived in Serbia at the worst period of an uncontrolled epidemic of lice-borne diseases. Its principal task was not the supply of extra clinical assistance, but the arrest of the epidemic by administrative and sanitary measures. The chief of these measures were the temporary cessation of railway traffic, the suspension of leave from the army, and the introduction of a widely applicable method of disinfection. The author demonstrates clearly the striking effect on the epidemic of both the cessation and the resumption of the movements of people.

By numerous charts and tables a large number of statistics of considerable scientific interest is recorded, and this, with the details given of the sanitary and preventive measures adopted, will be of value to all connected with the prevention of lice-borne and water-borne diseases in dealing with any future outbreaks on the Continent or elsewhere.

Benign Stupors: A Study of a New Manic-Depressive Reaction Type. By Dr. A. Hoch. Pp. xii+284. (Cambridge: At the University Press, 1921.) 14*s.* net.

AUGUST HOCH recognised the confusion arising out of the classification of certain functional psychoses as Manic-Depressive Insanity; he therefore set out to show that the elation and depression (from which the name has been derived) are of no more theoretical importance than other moods which characterise the group. The volume before us, edited by Dr. J. MacCurdy after the death of Hoch, is designed to show that the symptom-complex associated with apathy is as distinct as that of mania, and the book introduces the functional psychoses characterised by benign stupor.

The essentials of the stupor reaction are (1) more or less marked interference with activity; (2) interference with the intellectual processes; (3) affectlessness; (4) negativism. These and other symptoms which make up the clinical picture of the benign stupor are discussed in great detail and illustrated by numerous cases. Of particular interest is the peculiarity of the ideational content in its preoccupation with the theme of death, often to the complete exclusion of all other ideas.

A brief chapter is devoted to treatment, and stress is laid on the importance of stimulating the patient to exert as much effort as possible. The book is one of the most valuable contributions of recent years to psychiatric literature, and its editor is to be congratulated on the success with which he has carried out the task laid upon him.

Nerve Exhaustion. By Sir Maurice Craig. Pp. 148. (London: J. and A. Churchill, 1922.) 6*s.*

IN introducing the subject of nerve exhaustion, Sir Maurice Craig makes it evident that he is writing for the general practitioner rather than for the student of psychology. He particularly emphasises the importance of the prevention of nerve exhaustion, which is defined as "a state in which there is undue physical, nervous, or mental fatigue." The author considers that the essential factor leading to such a state is "hypersensitivity," which may be physical or psychical, and the recognition of which may enable one to prevent the onset of nerve exhaustion.

It follows from the definition that the condition has a very wide etiology and symptomatology, each of which is discussed under numerous headings. A separate chapter is devoted to sleeplessness and to the individual hypnotics which are used in the treatment of insomnia, but there is no mention of bromural, which is a safe and efficient sedative for most of the milder cases.

In the last chapter it is urged that the treatment of mental disorder should be freed from the legal restrictions which hamper it—restrictions which may have been necessary many years ago, but are now obsolete. The author considers that there are numerous cases of functional nervous disorder which should be allowed institutional treatment without the necessity of being certified, and he instances strong evidence in support of this.

The book will be of considerable value to the practitioner in the recognition and treatment of minor functional nervous disorders.

Guide to the Reptiles and Batrachians exhibited in the Department of Zoology of the British Museum (*Natural History*), Cromwell Road, London, S.W.7. Third edition. Pp. 56. (London: British Museum (Natural History), 1922.) 1*s.*

THIS publication is intended more for the general public than for the student of zoology. The author, whose name does not appear, has obtained a good balance in the treatment of the different groups of animals with which the little book deals. Exception must be taken to the statement that the Opisthoglypha, or back-fanged snakes, are, although poisonous, not dangerous. This is not always the case: the South African boomslang, *Dispholidus typus*, for instance, having in recent years been proved to be an extremely dangerous snake, there being more than one record of its bite having caused death in man. Experimentally it has been shown that the boomslang is more venomous than the cobra, puff adder, or any other justly dreaded South African snake.

Excellent in so many respects, it is a pity that so little pains have been taken in the correction of the proofs, some of the sentences, owing to lack of punctuation, being almost incomprehensible. This little guide, which is profusely illustrated by photographs of specimens in the museum, and by illustrations reproduced from the Cambridge Natural History, is, however, well worth the shilling asked for it.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Rat and its Repression.

I HAVE read with great interest the very able and exhaustive article by Mr. Alfred E. Moore in NATURE of May 20, p. 659, on the rat and its repression. As I have taken great interest in the question of rat suppression, I should like to add a few words to what Mr. Moore says.

If the campaign against these vermin were in such hands as his we should go a long way towards exterminating them, but the public does not take sufficient interest in a matter which they always think affects other people more than themselves. The result is that where one man makes a raid against his rats, twenty do nothing to suppress them, and perhaps ten others actually encourage their propagation by the carelessness with which they leave food and consumable stores unprotected.

One could have hoped that the Ministry of Agriculture would have taken up the matter seriously. The amount of damage done to food-stuffs is incalculable. Not only do rats raid our storehouses, but they also attack the crops almost before they are sprouting in the ground. Those who know Norfolk and Suffolk and any grain-growing district are familiar with the squeals of rats nesting in the hedgerows as they go along the roads, and when the seed-corn has been planted fields are covered with well-worn rat tracks, from which these rodents start to grub up the seeds from the ground and devour them. In December and January every field is covered with rat scratchings, which means that so much corn has been devoured. The loss to the farmer is very great and, of course, the public participates in this.

Piecemeal suppression is of little use, as rats are great travellers, but if a sufficient effort were made by the Ministry of Agriculture to stir up local authorities and to provide some funds, which would not amount to very much, to help them, we should have a remarkable result in the clearing from our fields and our food stores of these destructive vermin. The Treasury will sanction millions for unproductive expenditure. Any minister can get practically what he wants for his own particular hobby, but in this matter of real usefulness where capable local administration is at hand, our custodians of the public purse refuse to assist in any way.

Individual philanthropists cannot be expected to find money for a public cause when the representatives of the public stand idly by. What remedy have we for this? Only one; which is that we should put pressure locally upon our parliamentary representatives and send up communications to the Ministry of Agriculture, urging upon them the necessity of some sort of action.

I hope this advice will not fall upon barren ground. There are plenty of men in both Houses of Parliament who will be very glad to help in pushing this agitation forward.

ABERCONWAY.

43 Belgrave Square,
London, S.W., May 24.

The Blue Flame produced by Common Salt on a Coal Fire.

The blue flame produced by sprinkling salt on a glowing coal fire is a good example of common knowledge, which, not finding a niche and an explanation in text-books, becomes a recurrent topic of inquiry and discussion in scientific journals. It may perhaps be of interest if I add a historical note to what Prof. Merton has stated in Nature of May 27, p. 683.

The blue flame in question appears to have been first treated from the spectroscopic standpoint by the late Dr. J. H. Gladstone in 1862 in a letter to the *Philosophical Magazine* (ser. iv., vol. 24, p. 417). Without being quite conclusive he seems to have regarded copper chloride as the source. The matter was raised again by an anonymous letter to Nature in 1876 (vol. xiii. p. 287), and a discussion has recurred from time to time in these columns from that date until 1890. Full references to this are to be found in Kayser's "Handbuch der Spectroscopie," vol. v. p. 391. A communication to Nature by T. N. Müller in 1876 (vol. xiii. p. 448) seems to have hit the mark. He recognised the flame as being like that of copper chloride, and, surmising that the source of the copper lay probably in the pyrites of the coal, found that the blue flame did not appear when salt was sprinkled on a glowing fire of charcoal. The matter was clinched by Salet in 1890 (*Comptes rend.* 110, p. 282), who identified the spectrum with that of copper chloride as carefully mapped by Lecoq de Boisbaudran, and he actually isolated metallic copper from the fuel ash.

The blue flame given by salt always seems to me distinguishable from that of carbon monoxide, and appears very bright by contrast with the yellow-red glow of the fire. It is somewhat surprising to see how far the yellow sodium flame is suppressed.

Arthur Smithells.

The University, Leeds, May 28.

Optical Resolving Power and Definition.

In Nature of May 27, p. 678, Mr. A. Mallock suggests as a quantitative measure of "definition" in an optical instrument "the angular or linear size of the field of view compared with the smallest corresponding quantity which can be clearly distinguished," and proceeds to extend "definition" on an equivalent general basis to a number of other instruments.

Whether or not this proposal will serve a useful purpose in other directions need not be discussed here, but in the case of optical instruments the measure proposed will not commend itself to opticians, for it involves a radical change in the accepted meaning of "definition" in this connection. The suggestion in fact amounts to nothing more than the measurement of the angular field of view in terms of a unit which varies with the aperture of the lens and the wave-length of the light which is used, a proposal which surely carries its own condemnation in its enunciation. That the ratio in question is worthless as a measure of "definition" is obvious from the consideration that in many instruments, at say the centre of the field, the resolving power and the "definition"—that is the degree to which details of an object are clearly discernible in its image—may remain unaffected while the field of view is greatly changed by an alteration in the size of a suitably placed stop. Conversely in apparently similar instruments the "definition" may vary appreciably from one instrument to another while the field of view and the resolving power are alike in all cases.

The distinction between resolving power and definition is real but not easily defined in a few words. The former deals with the discernment of separate sources of such apparent minuteness that it cannot be claimed that the image indicates with any accuracy the shape of the source itself. The latter is concerned with the sharpness of the apparent image outline of larger objects. The former depends primarily on the dimensions of the first dark ring in the image of an apparently point source, and the conditions of observation require the range of wave-lengths of light forming the focussed image to be limited. The latter depends more upon the broad light distribution in the diffraction pattern than upon the alternations of light and darkness, and the range of wave-lengths is not an important factor. As the size of the rings is not greatly affected by small amounts of aberration, the resolving power is not a suitable measure of the correction of a lens system, but it is precisely upon the degree to which aberrations are removed that definition depends. Of two photographic lenses with the same resolving power, and the same field of view, one may give brilliant pictures because the definition is good and the other comparatively flat pictures because the definition is poor. To the user of simple instruments definition is of great importance, resolving power does not concern him.

This is not a suitable occasion on which to discuss the measurement of "definition" or the standards which are suitable for application to various types of instrument. The subject is one of great difficulty particularly in view of our ignorance of the extent to which it is possible to eliminate aberrations in systems of simple construction. Lest, however, readers of Nature should be misled it cannot be too emphatically stated that in omitting from "definition" its most essential factor and substituting therefor an independent conception, Mr. Mallock's attempted generalisation is likely to prove only a cause of confusion to those who hope to measure the merits of optical instruments by its means.

T. Smith.

The Difference between Series Spectra of Isotopes.

Prof. P. Zeeman mentioned to me recently some new measurements of the absorption spectrum of lithium which he undertook in order to prove the presence of both isotopes. It seems to me, that at the present time it is not certain what one should expect here theoretically. Bohr's formula for the change in the frequency ν due to the motion of the nucleus has been applied by him only to the cases in which a *single electron* moves around the nucleus; namely, to H and He^+. Recently the formula has been also applied by various authors (see F. W. Aston, "Isotopes," p. 123—London 1922) to the calculation of the difference between series spectra of isotopes; this means to atoms in which *several electrons* move around the nucleus. So far as I know there are as yet no investigations on the equation which must for these cases replace Bohr's equation

$$\nu_2 : \nu_1 = \frac{M_2}{M_2 + m} : \frac{M_1}{M_1 + m} \quad . \quad . \quad . \quad (1)$$

(M_1, M_2, m are respectively the masses of the nucleii of the isotopes and of the electron; ν_1, ν_2 are the frequencies of corresponding lines).

In the case of one electron only, (1) follows immediately from the well-known transformation of the "problem of two bodies" from absolute to relative co-ordinates (see, *e.g.*, Whittaker, "Analytical

2B 2

Dynamics," § 46). For several electrons there is no similar simple transformation. The "radiating" electron compels the remaining electrons to execute motions of reaction, which also influence the nucleus.

Probably it will be possible to derive a sufficiently approximate formula for the case of the p- and d-motions of lithium. This must be very difficult, however, for the case of the 1·5 S-path. The fact that at all events equation (1) cannot be true in general for atoms with several electrons will be shown by the following example (though of course on account of the Principle of Correspondence not representing a process really occurring in nature): two electrons move around the nucleus in a centrally symmetrical configuration, at first in a two-quantum and then in a one-quantum circle. By symmetry the nucleus remains continually at rest. In this case therefore the liberated energy and, consequently, the radiated ν would, contrary to (1), be exactly independent of the mass of the nucleus. P. EHRENFEST.

The University,
Leyden, Holland.

I SHOULD like to add a few remarks to the interesting letter of Prof. Ehrenfest about the contents of which he was so kind to inform me before publication. As pointed out in his letter, the effect of the mass of the nucleus on the spectrum of an atom, containing more than one electron, is a complex problem which depends on the electronic arrangement in the states of the atom, involved in the emission of the lines, in a way which has hitherto not received sufficient attention. Not only may the mass effect disappear completely in such cases, where several electrons move round the nucleus in equivalent orbits, but, as indicated by Prof. Ehrenfest, this effect may also in case of the motions which we actually meet in the emission of the series spectra be different from that calculated for an atom with one electron.

Although in the emission of these spectra we are concerned with motions whereby a single electron moves in an orbit different in type from the orbits of the other electrons, the problem differs essentially from the problem of two bodies in celestial mechanics. Thus according to the picture of atomic constitution, outlined by the writer in two letters to NATURE (March 24, 1921, October 13, 1921), we shall assume that the electron connected with the emission of the series spectra, although during the larger part of the revolution it remains outside the configuration of the electrons in inner groups, it will nevertheless in certain states penetrate into the interior of the atom during its revolution. The fact that the electron in the inner loop of its orbit is subject to large forces is of preponderant influence as regards the fixation of the energy in the corresponding stationary states of the atom. For such a motion the effect of the nuclear mass might differ essentially from that estimated from an examination of the mechanical properties of the motion in the outer loop only, and the question arises, whether the mass effect is sufficiently large to account for the discrepancies, observed by Merton, in the wave-lengths of certain lines in the spectra of lead isotopes, which although very small are yet much larger than those to be expected from the simple formula quoted in Prof. Ehrenfest's letter.

Although this question seems difficult to settle without a closer investigation, it would scarcely appear probable that the answer will be affirmative. On the other hand, it cannot be excluded that the discrepancies in question are due to a slight difference in the field of force surrounding the nucleus, arising from the difference in the internal nuclear structure of the lead isotopes. This possibility has been discussed from various sides. At first sight we meet with the difficulty, that the dimensions of the nucleus (*ca.* 3×10^{-12} cm.), estimated from experiments on the scattering of α-particles, are exceedingly small in comparison with the dimensions of the orbits of the electron responsible for the emission of the series spectra, which are of the order 10^{-8} cm. or larger.

This difficulty may disappear, however, by considering the circumstance mentioned above, that in certain states the series electron during a short interval of its revolution penetrates deeply into the interior of the atom. In fact, we must assume, that this electron in the states corresponding to the S-terms of the series spectra penetrates to even smaller distances from the nucleus than the electrons in the innermost group of the atom, the dimensions of which are in lead smaller than 10^{-10} cm. To the possible importance of this point in connection with the spectra of isotopes my attention was kindly directed by Dr. Kramers in a discussion about Prof. Ehrenfest's letter. N. BOHR.

University, Copenhagen.

The Destruction of Mosquito Larvæ in Salt or Brackish Water.

A NUMBER of experiments on the destruction of mosquito larvæ by the well-known system of "surface oiling," carried out at Hayling Island during the year 1921, supplied further evidence of the fact that this method is not one of universal application. The production of an unbroken film of a sufficiently lasting nature is sometimes an impossible task, notably in cases where the water surface is broken up by growths of reeds, etc., or is too freely exposed to the wind. In cases of this kind it is necessary to discard the oil film in favour of a "larvicide," that is to say, a substance which, by mixing with the infested water, will destroy the larvæ.

Unfortunately, however, practical information concerning larvicides is difficult to obtain. In the literature of the subject references are to be found to a number of suggested substances, but the vast majority of these stand self-condemned owing to the prohibitive cost that would be entailed by employing them in the prescribed "strengths" on any practical scale. A large number of these larvicides are, moreover, admittedly ineffective when added to brackish or salt water, and are consequently of little value in districts such as Hayling, where the salt-water mosquito, *Ochlerotatus detritus*, is the principal offender.

A number of tests have recently been carried out in the laboratory of the Hayling Mosquito Control, in the hope of discovering a larvicide which could be used successfully (and at a low cost) in salt, or partly salt, water. It was found that a liquid containing 15 per cent of soluble cresol, sold as a disinfectant under various names, gave very promising results in the laboratory. This liquid, at a dilution of 1 in 16,000, was found to kill the larvæ of *Ochlerotatus detritus* in one hour; at a dilution of 1 in 32,000, in one and a half hours; and at a dilution of 1 in 48,000, in three and a half hours. In the majority of these experiments the water containing the larvæ was of a salinity about half that of sea water.

In order to test this larvicide on a larger scale, a shallow stretch of brackish water adjoining the Hayling Golf Links was selected for experiment. This water was very heavily infested with the larvæ

of *Ochlerotatus detritus*, together with a large number of pupæ. Titration experiments carried out by Mr. Lyon Turner showed that the salinity of the water was 49 per cent. that of pure sea water.

After estimating the volume of the water as 20,000 gallons, it was decided to use the larvicide in the proportion of 1 in 16,000, the quantity required being therefore 1·25 gallons. The result of the experiment was entirely satisfactory, a thorough examination on the following day failing to detect a single live larva or pupa. Further examinations were made with the same result on April 26 and May 2, and on May 5 the success of the experiment was further confirmed by an examination made by Mr. P. G. Shute (Ministry of Health Laboratory).

Two other ponds badly infested with the larvæ of *Ochlerotatus detritus*, and containing a large number of pupæ, have since been treated with like success, a thorough examination of both ponds being made on the following day without a single live larva or pupa being found.

It was noticed during the experiments that the addition of the larvicide to one of the ponds in which the water was only slightly saline, produced the characteristic "milkiness" associated with the use of disinfectants of this class. In treating the other ponds where the water was of greater salinity, this cloudy appearance was not produced, although the results obtained in all the three experiments were equally successful. A series of laboratory tests showed that the "milkiness" occurred whenever the proportion of sea water to fresh water was less than 1 in 7, the cloudy appearance being uniformly distributed through the water treated. When the larvicide was added to water of greater salinity, it diffused in the form of minute globules. It was suggested by Mr. P. G. Shute that, in cases where the proportion of sea water exceeded one-seventh, the milkiness (and the accompanying uniform diffusion of the larvicide) might possibly still be produced if the larvicide were diluted with a small quantity of *fresh* water before use. Experiment showed this to be the case, and this preliminary dilution is obviously to be recommended whenever the larvicide in question is to be added to water of appreciable salinity.

It is probable that successful results will be obtained with even smaller proportions of the larvicide than those employed up to the present, since the effects produced with dilution of 1 in 48,000 indicate that the limit has been by no means reached. Further experiments in this direction are now in progress.

It is important to note that water treated with this larvicide in the proportions mentioned is quite harmless to human beings or animals drinking it accidentally.

The comparative cost of "larviciding" and "paraffining" in any given case depends, of course, upon the depth of water to be treated. In cases where the water is shallow there is little to choose as regards expense, even when the larvicide is used in as large a proportion as 1 in 16,000. If d be the depth of any particular sheet of water in inches, n the "dilution" (or the number of parts of water which can be treated by one part of the larvicide), and c the ratio of the cost of the larvicide to that of paraffin, then the ratio of the expense of "larviciding" to that of "paraffining" has been shown by Marshall (*Science Progress*, January 1922, p. 468) to be given by the expression

$$(1500 \times c \times d)/n.$$

In the case of the first pond referred to above, d was 3 inches and n was 16,000. The price of the fluid was 5*s*. 9*d*. a gallon, so that c may be taken as 4. Hence the relative cost of the operation, compared to paraffining, was

$$(1500 \times 4 \times 3)/16,000, \text{ or } 1·125,$$

the actual cost of treating the 1420 square yards of pond being about seven shillings. It should be noted, moreover, that as the water surface in this case was much exposed to wind, paraffining carried out on previous occasions had proved quite ineffective.

Since a cubic yard is the space occupied by 168 gallons, it will be found that the number of gallons in any piece of water is $(A \times d)14/3$, where A is the surface area in square yards and d is the depth in inches. So that, if the larvicide is to be used in the proportion of 1 in n, the number of gallons required will be $14/3(A \times d)/n$ gallons. This is a useful formula for calculation, particularly when a definite value of n has been decided upon for treating a number of ponds.

JOHN F. MARSHALL.
Seacourt, Hayling Island, Hants.

The Teaching of Natural History in Schools.

IN an article which appeared in NATURE, May 13, p. 628, dealing with the memorandum of a British Association Committee on this subject, the following statement occurred: "It devolves on the teachers of zoology to show in detail the kind of zoological syllabus that can be put into operation in schools as a basis for zoological teaching." May I be allowed, as one whose privilege it has been to teach zoology to some hundreds of boys, to offer one or two suggestions for such a syllabus?

The writer of the article was entirely favourable to the spirit of the memorandum, as indeed are a great number of persons responsible for the direction of education. With regard to the younger generation, the learners, the question is answered with no uncertain voice. I have put the choice of zoology or botany to forms of boys of all ages from 14 to 18, and have found invariably that 90 per cent. or more vote for the teaching of zoology. It may be that the boys scent my personal leaning towards zoology (though I try to be impartial) or, again, that they regard the study of animals as a more masculine pursuit than the study of plants. At the same time, it is evident that the boy's mind shows a genuine thirst for a knowledge of animal life.

There are two aspects of the application of zoology to the school curriculum. On one hand, there are the older boys who are being trained for some definite profession—medicine, agriculture, biological research, and so forth. On the other, there are large numbers of younger boys, very few of whom will ever require zoology as a professional subject, who are being taught biology as part of their general education. Zoological syllabuses for the professional examinations are issued by the various universities; moreover, in the Higher Certificate Examination zoology may be offered as a group subject. Thus, in the case of senior boys the biology master has ample guidance in the general requirements of a zoological education, and can develop and extend his teaching accordingly; but in teaching zoology to younger boys the master has to evolve his own syllabus and to form his own standard of attainment. It is with the latter aspect of the subject that I propose to deal.

The boy of fourteen when he comes to the study of biology requires something more substantial than

what is generally implied by "nature study." He is perfectly capable of appreciating the elementary conceptions of anatomy and physiology. He is, moreover, fully alive to questions of sex, and is ready to assimilate a clean scientific view of its meaning. Personally I should find it very difficult to teach either botany or zoology apart from one another to these young boys.

Botany may be offered as a subject both for the Lower and School Certificates; but there is no indication from higher authority as to what should be included in a course of zoology for boys of this standard. It has been necessary, therefore, to substitute special syllabuses in biology of our own making, in order to enforce the inclusion of zoology in the examinations. Two examples are quoted below of the zoological content of biological syllabuses for the Lower Certificate:

A. Boys of 14½-15½, working four hours a week for three terms.

Elementary outlines of anatomy of following: Earthworm, Frog, Rabbit.

Prevention and destruction of insect pests, Elaters (wireworms), Tipulidæ (leather jacket), Aphididæ (woolly aphis).

Special scheme of Research Work.

(*a*) British Bird Life: (i.) Embryology; (ii.) General Anatomy of Birds. The mounting of specimens, examination of beaks and crops in connection with cultivation.
(*b*) Coleoptera, Lepidoptera, Hymenoptera.
(*c*) Anatomy of Farm Animals.
(*d*) Diseases of Animals; Blood.
(*e*) Insect Pests of English Fruit Trees.

One group only has been taken by any boy. Special work has been done by the whole form in preparation of charts, recording agricultural operations, bird life, etc., during the different seasons, and meteorological observations taken daily.

B. Boys of 14-15, working two hours a week for three terms.

A general knowledge of the Natural History of animals, with special reference to British forms (*e.g.* Rabbit, Pigeon, Frog, Snail, Butterfly, Spider). The study of pond life.

The general facts of fertilisation, and embryology of the frog and chick.

Use of the microscope for the study of Protozoa and Crustacea, also for parts of higher animals (*e.g.* scale of fish, feather, squamous epithelium from human cheek).

A general idea of organic evolution.

The above syllabuses, and others of a similar nature, have been successfully carried out. They are, however, open to criticism as not being suitable for wide application, especially in schools where monetary considerations constitute a limiting factor. In the absence of a recognised syllabus for a first introduction to zoology, and with a view of showing how the subject can usefully be introduced in any school, the writer has prepared a small text-book, the zoological syllabus of which is as follows:

Frog—External features, mode of life, respiration, alimentation. Development; breeding, segmentation, tadpole life, metamorphosis.
Earthworm—Habitat, mode of life, external features, general dissection, reproduction, soil action.
Fishes—Dogfish and Cod; habitat, mode of life, external features, development. Scales as a means of age-determination.
Arthropods—Crayfish, Bluebottle Fly, Garden Spider; habits, external features, life-cycle. Comparative table and summary of leading characteristics of each class.
Insect Pests—(An introduction to economic zoology.) Cabbage White Butterfly, Winter Moth, Cockchafer, Bean Weevil, Click Beetle (wireworm), Bean Aphis, Crane-fly (leather jacket), Larch Saw-fly.
Skeleton of the Vertebrate Fore-limb—Perch, Frog, Pigeon, and Rabbit. Comparative table.
Elementary conceptions of Variation and Heredity. Evolution.
The Microscope—Its use; suitable objects for observation. The nature of living matter; the cell. (For schools where the microscope is available.)

This syllabus is in close accordance with the general scope of teaching advocated by the British Association Committee, but is so condensed as to be covered by one hour's work a week throughout one school year. Types which, either through their limited distribution or their expense, may be difficult to obtain have been omitted; it is fatal to begin the study of zoology from a book instead of from an animal.

Finally, although a precise syllabus is necessary for the successful prosecution of class work during school hours, the best interests of zoology will never be served by that means alone. The museum and the aquarium must be going concerns, continually renewed and augmented by voluntary labour cheerfully given out of play-hours.

E. W. Shann.

The School, Oundle, May 16.

Every teacher of biology in public schools will naturally welcome both the original memorandum of the British Association and also the article signed F. K. in Nature of May 13, p. 628. The greatest difficulty in the teaching of biology at public schools at the present time is the position of the teacher. Unlike the teacher of so many other subjects the biologist is not turned out more or less a master of his subject, but is just in a position to begin to learn it, and the subject or subjects are so vast that if he is to do his work conscientiously he has a life's task before him. Of course this is more or less true of every other subject, but I think I am not in serious error when I say that a man with a good classical degree probably finds himself sufficiently well equipped to cope with the really intelligent boys of the upper sixth of the average public school.

So vast is the subject of biology, however, that the teacher cannot hope to cope with the really clever boy unless he is a real student of his subject, and even then of course his influence is that of a slightly superior but at the same time a fellow student, and not that of a master.

The teacher of biology, if he is to carry on his work successfully, must have an average knowledge of a great deal besides his text-book of botany or zoology. He must have a practical working knowledge of microscopy, pond-life, marine biology, field botany, including a reasonable knowledge of mosses, lichens, rusts, and other fungi. One knows, of course, that the mind of the average schoolboy is somewhat limited, but there are always a few that are capable of doing really good work, and for such boys the position of the master must be either one of suppression or that of a fellow-student, and one is seriously led to think that too often the work of the teacher is an act of suppression.

To sum up the whole position, a teacher of biology must be prepared to make his subject his life's work. It is lamentable, however, that even in some of the greatest of our public schools there is little room for the progressive student. The chief form of recognition or promotion consists of extra duty, and it is just this extra duty that puts an end to the idea of study. If a man is to teach biology properly he cannot hope to satisfy the demands of the headmaster who looks for a colleague who will take an active part in the games of the school and a commission in the Corps, etc., and yet unless a man does do these things his chances of success in the scholastic world are poor. Of course things are improving and the high standard of work demanded by university scholarships is making the position of the true teacher a more important one.

I do not think, however, that F. K. is quite just when he advocates a vigorous protest against the opinions of examiners. The universities are naturally anxious to get hold of the best boys available, and they are surely the best men to select their material. We know that all examinations are more or less unsatisfactory, but they are the only possible method.

The chief fault lies in the lack of co-ordination between the university and the public school, and this is not altogether the fault of the university.

A. G. LOWNDES.

α-Particles as Detonators.

WHEN an α-particle passes through matter it may be considered that the matter in the proximity of the path of the swiftly moving particle is momentarily raised to a high temperature. Looked at in this light the action of an α-particle may be likened to that of a detonator and it may be possible to detonate a sufficiently unstable substance by the action of these particles. This has been found to be the case with the familiar explosive compound, nitrogen iodide.

The experiment forms a rather striking lecture demonstration. Nitrogen iodide is prepared in the usual way by the mixture of finely ground iodine and strong ammonia and allowed to dry overnight in the open air. On bringing a fairly strong radioactive source (say the active deposit of radium) within 3 or 4 cms. of the compound the iodide explodes. It may readily be shown by the use of screens of suitable thickness placed over the source that the result is due to α and not to β or other rays.

Detonation is not caused by the first α-particle which happens to strike the substance, but seems to be a probability effect. With a button of nitrogen iodide of about 0·1 cm.^{2} area a source of radium-C equivalent in γ-ray activity to about 3 mg. of radium placed 1 cm. away causes the button to explode in about 20 seconds, *i.e.* when between 10^7 and 10^8 α-particles have struck it. Increasing the size of the button or the strength of the source decreases the time necessary. Quantitative measurements are not very accurate, as it is difficult to ensure identical conditions of experiment. Doubtless other unstable compounds might be found which would also be exploded in this manner.

G. H. HENDERSON.

Cavendish Laboratory, Cambridge, May 23.

Active Hydrogen and Nitrogen.

Two brief comments are suggested by the interesting work of Dr. F. H. Newman on the activation of hydrogen and nitrogen described in the *Philosophical Magazine* for March. The failure of the reaction product of the active nitrogen with sulphur, phosphorus, and iodine to give a test for nitrides is not evidence of the absence of a chemical reaction between those elements and nitrogen, for all three are more electronegative than nitrogen and the compounds formed would be sulphides, phosphides, and iodides, respectively. That this is in fact the case is shown in some experiments of mine with Dr. A. C. Grubb, which are now in process of publication, in which tests for sulphides and phosphides were actually obtained after exposing the corresponding elements to a stream of active nitrogen formed in the corona discharge. Our experiments did not include iodine.

Further, the evolution of gas when the bulb, in which these same three elements had been exposed to active hydrogen, was heated from −40° C. to 100° C. is not evidence of the failure of these elements to react with the active hydrogen, for the compounds formed would be hydrogen sulphide, phosphine, and hydrogen iodide, all of which are gaseous at the latter temperature though liquefied at the former, and would thus be evolved in the gaseous form when heated to increase the pressure as noted. Here again my experiments with Dr. R. S. Landauer and with Dr. William Duane, already published, show that phosphine and hydrogen sulphide are actually formed, the latter being confirmed by the dynamic method of Dr. Newman.

GERALD L. WENDT.

Chicago, Illinois, U.S.A.

IN reply to the comments made by Prof. Wendt, although no traces of the nitrides of sulphur, phosphorus, and iodine were found in the experiments on the activation of nitrogen, this was not unexpected, as it was considered highly improbable that any chemical compounds formed would respond to the nitride test. As the absorbed gas was not reliberated on heating, it appeared that chemical combination had taken place, the compounds so produced being very stable. Several other elements actually formed nitrides with the active nitrogen. These two facts suggested that chemical compounds were produced. The experiments of Prof. Wendt, now in the course of publication, seem to confirm this view.

As regards the action of active hydrogen on these three elements, it was found that at temperatures above 0° C., absorption of the gas occurred, although at a decreased rate. At these temperatures, if the chemical products formed are hydrogen sulphide, phosphine, and hydrogen iodide, they must be present in the gaseous state. There are other factors to be considered in order to account for the disappearance of the hydrogen, for the production of these gases will not explain the decrease in pressure. They are probably "trapped" within the solid present in the tube, and only reliberated on heating. Some of the gas which was evolved on the application of heat was re-absorbed when an electric discharge was passed through it, or when exposed to α-ray radiation. This re-absorbed gas was hydrogen, which may have been produced by the dissociation of the chemical compound formed originally, or it may have disappeared originally by occlusion within the solid. Although chemical action does account for the disappearance of some of the hydrogen, other processes, such as occlusion, have to be taken into account.

F. H. NEWMAN.

University College, Exeter.

A Supposed Ancestral Man in North America.[1]

By Dr. A. SMITH WOODWARD, F.R.S.

PROF. H. F. OSBORN has just described a water-worn small molar tooth from a Pliocene formation in Nebraska, U.S.A., as the first evidence of an anthropoid primate discovered in the New World. The specimen was found in the Snake Creek beds by Mr. Harold J. Cook, who has already made known numerous important remains of Pliocene mammals from Nebraska, some showing marked Asiatic affinities. With the aid of Drs. W. D. Matthew, W. K. Gregory, and M. Hellman, Prof. Osborn has determined the tooth to be a second upper molar, and he has named the unknown genus and species to which it belonged *Hesperopithecus haroldcookii*. It is nearly as large as the second upper molar of an American Indian, and its two diameters are almost equal. The kind of wear shown by its evenly concave coronal surface "has never been seen in an anthropoid tooth." In type the tooth is "very distant" from the corresponding tooth of the gorilla, gibbon, and orang; it is "still very remote" from that of a chimpanzee. It is also "excluded from close affinity to the fossil Asiatic anthropoid apes" represented by teeth found in India; and "it cannot be said to resemble any known type of human molar very closely." Indeed, "it is a new and independent type of Primate, and we must seek more material before we can determine its relationships."

The statements quoted make it difficult for one who has not seen the tooth to understand why Prof. Osborn even refers it to a Primate; and the published figures are not very helpful. The crown may be described as nearly triangular in shape, with bluntly rounded angles, a slightly raised and partially crimped rim surrounding a gently concave surface. The root is very massive, and at a considerable distance below the crown it becomes bifid, the smaller portion extended beneath one margin of the crown, the larger portion beneath and inclined towards the opposite apex. On one side of the root, between the bifurcation and the crown, there is an irregular indentation, from which Prof. Osborn supposes a third root-fang has been broken away. No stump of this third fang, however, is shown in the drawing.

In determining the tooth to be an upper molar, Prof. Osborn regards the edge with the smaller portion of root as external, and the tapering opposite end with the larger portion of root as internal. The hypothetically restored piece of root thus becomes posterior. It is, however, equally reasonable to interpret the so-called external border as anterior and the tapering end as posterior. If, then, the indented lateral portion of the root never bore another fang, the tooth becomes a lower molar. If this interpretation be admitted, comparison should be made not with any Primate tooth, but with the last lower molar in the primitive bears. In general appearance and shape the crown is very suggestive of that of the last molar in the lower jaw of some species ascribed to Hyænarctos and related genera; and as primitive bears of this group are already known by several fragments from the Pliocene of North America, material will eventually be available for comparison. The root of the last lower molar of Hyænarctos unfortunately appears to be unknown; but in the modern Ursus, in which the tooth in question is extremely variable, the root is often bifid, as in the new fossil from Nebraska, while between the bifurcation and the crown there is a hollowing of its outer face. There is, indeed, some reason to suspect that Hesperopithecus has received an inappropriate name.

[1] H. F. Osborn, "*Hesperopithecus*, the first Anthropoid Primate found in America," American Museum Novitates, No. 37 (reprinted, without figures, in *Science*, vol. 55, pp. 463-465, May 5, 1922).

Synthetic Dyes as Antiseptics and Chemotherapeutic Agents.

By Prof. C. H. BROWNING, University of Glasgow.

GENERAL interest in this subject has been recently stimulated by accounts in the daily press of a communication to the Society of Chemical Industry at Manchester by Messrs. Fairbrother and Renshaw.[1] The fact, however, ought not to be overlooked that much work has been in the past devoted to these problems by a number of investigators. That certain dyes of the triphenylmethane class possess marked antiseptic properties has long been known. Thus Stilling[2] in 1890 noted the powerful effect of ethyl violet on staphylococci (one of the commonest group of organisms which cause suppuration). He suggested the use of a mixture of allied dyes in the treatment of infective conditions, especially of the eye. But Stilling's suggestion found little favour with practical surgeons. As compared with phenol or mercuric chloride, the antiseptic dye-stuffs in general exert their lethal action on bacteria relatively slowly; thus, when tested by the usual method, in which only a brief period of contact between the organisms and the chemical agent is permitted, these dyes appear to act very weakly. It is probably for this reason that they were neglected.

The fact was overlooked that from the beginning of contact very high dilutions of antiseptic dyes may inhibit bacterial activity and that such "bacteriostatic" action can be utilised advantageously for therapeutic purposes. Churchman,[3] however, in America has investigated more recently the allied product, gentian violet, and has emphasised its value in the treatment of certain local pyogenic infections. The diaminotriphenylmethane dyes, malachite green and brilliant green, were shown to be actively antiseptic by Drigalski and Conradi[4] in 1902, and brilliant green has been applied with success in the treatment of infected wounds.

Investigations carried out with the view of comparing the antiseptic properties of various classes of dyes by Browning and Gilmour[5] confirmed the fact that a considerable number of basic compounds showed

such action; the series of compounds which they investigated included the acridine group, triphenylmethane group, indamines, azine dyes (safranin), thiopyronin, and thiazines (methylene blue). A continuation of this work showed that of all the substances examined diaminoacridine derivatives ("acriflavine" and "proflavine") stand out on account of a combination of three characteristics, namely, high antiseptic potency, low toxicity for mammalian tissues, and insusceptibility to the interfering action of serum proteins, which diminish markedly the efficacy of all other powerful antiseptics hitherto tested. Therefore these substances, the antiseptic properties of which had not been recognised before, have been widely employed for the treatment of localised pyogenic infections, *e.g.* in wounds; when suitably applied, their use has proved highly beneficial. Recently also non-ionised compounds of mercury with dyes of the eosin group have been successfully used in America (mercurochrome of Young, White, and Swartz).[5A] In the case of generalised infections, however, the therapeutic problem is attended by much greater difficulties, and there is probably no synthetic compound so far available which will exert curative action in generalised bacterial infections in the human subject.

SELECTIVE ACTION.

When the antiseptic potency of a series of compounds is determined for organisms of various types, striking instances of selective action are met with, *i.e.* one compound will act very powerfully upon a particular organism and be relatively inert toward another; other compounds may exhibit the reverse order of activity on the same two organisms. Selective action of this kind was noted by Rozsahegyi [6] in 1887. Probably the most striking example of this is exhibited by the cyanine dye, "sensitol red," the ratio of the sterilising concentrations for *B. coli* and *Staphylococcus aureus* being probably greater than 2000 : 1 (Browning, Cohen, and Gulbransen).[7]

RELATIONSHIPS BETWEEN CHEMICAL CONSTITUTION AND ANTISEPTIC ACTION.

Within narrow limits, in groups of closely related compounds, certain laws have been established. In the triphenylmethane series, both with the diamino and the triamino derivatives, the substitution of methyl and ethyl groups in the amino radicals has been found to enhance the antiseptic action. Thus the penta- and hexamethyl triaminotriphenylmethane dyes, methyl violet and crystal violet, have been found by Dreyer, Kriegler and Walker,[8] and others to be more potent against staphylococci than the unsubstituted analogues, rosaniline or parafuchsine; similarly malachite green (the tetramethyl diamino derivative) and brilliant green (tetraethyl derivative) are much more powerful than the unsubstituted diaminotriphenylmethane dye, Doebner's violet.[5] In the acridine and azine series it has been established that potency of action in a serum medium is a characteristic of the diamino derivatives which have an alkyl group attached to the medial nitrogen atom (Browning, Cohen, Gaunt, and Gulbransen).[9] But general principles correlating chemical structure with antiseptic action cannot be formulated in the present state of knowledge. There is certainly no relationship between colour and effect on micro-organisms.

ACTION ON PROTOZOA.

Ehrlich and Shiga [10] discovered that by means of injections of a benzidine dye, which they named trypan red, mice infected with the trypanosomes of the South American horse disease, *mal de caderas*, could be completely sterilised; thereby an otherwise acutely fatal infection could be cured. This work gave the impetus to the search for chemotherapeutic agents, and the greatest success achieved in this line has been the discovery of the "salvarsan" group of compounds by Ehrlich and his co-workers. In this department of research, again, it is impossible so far to enunciate general principles which should guide us in the search for effective substances. The therapeutic action is frequently not simply that of an antiseptic operating in the tissues and circulation of the infected animal; thus *in vitro* the parasites of *mal de caderas* are not killed by concentrated solutions of trypan red. Further, selective action is exhibited to a very marked degree by chemotherapeutic agents in protozoal infections; the efficacy of quinine in malaria and its relative inertness in trypanosomiasis is an instance of this. Certain compounds, however, are lethal for protozoa *in vitro* in concentrations which permit bacteria, of some species at least, to survive. Fairbrother and Renshaw suggest that such substances may be utilised with advantage in circumstances in which the process of bacterial purification of sewage fails, owing, it is believed, to an overgrowth of certain protozoa destroying the bacteria.

The search for chemical substances which shall exert curative effects in bacterial and protozoal infections appears to be well worth pursuing, since there are many diseases in which it would seem to be impossible to influence to a significant extent the natural defensive mechanisms of the body by procedures of specific immunisation; tuberculosis is an outstanding instance. But the successes hitherto achieved, especially in protozoal and spirochætal diseases (quinine in malaria, salvarsan in syphilis and other spirochætal infections, trypan blue in piroplasmosis, and emetine in amœbic dysentery), and the promising results in certain bacterial diseases (diaminoacridine derivatives, triphenylmethane compounds and mercurochrome in local pyogenic infections, and ethylhydrocuprein in experimental pneumococcus infections) are still more or less isolated phenomena. If it be possible to establish general principles in chemotherapy, this result will only be attained by much further investigation.

The 700th Anniversary of the University of Padua.

By Prof. E. W. SCRIPTURE.

THE university of Padua was founded by professors who migrated from Bologna in 1222 owing to oppressive regulations. It very rapidly became great and famous. For nearly 500 years it was one of the leading universities of Europe.

The development of English culture and religion was strongly influenced by the earlier English students of Padua, comprising Linacre, Latimer, Tunstall, and Pace. English science received a splendid glory by Harvey's discovery of the circulation of the blood, in the anatomical theatre of Padua, and it was the inspiration of great thinkers, like his professors Galileo, Acquapendente and Casserio, that stimulated his active mind to a new thought. Evelyn, one of the founders of the Royal Society, was a student here; at his house many of the influential figures of England appeared. Sherard, who founded the chair of botany at Oxford, laid out the Oxford Botanical Gardens on the model of those of Padua, the oldest in Europe. Dr. Caius, the founder of Caius College, was also a student at Padua.

Viewed as a national university Padua is a brilliant success. Its medical school is excellently equipped. Its faculty includes Luccatelo (medicine), Bassini and Donati (surgery), Belmondo (psychiatry), and Casagrande (hygiene). It has a special school of hydraulics, a subject of such importance that Italy has established a special Ministry for it. Its equipment in geology and palæontology is in some departments unequalled anywhere else. In law it is almost, perhaps quite, the first place in Italy. In history the name of Manfroni at once comes to mind. When it is considered that all the students are post-graduate and professional (no undergraduate), Padua ranks certainly with the best universities of England and America.

The glory of Padua lies in the great men who once taught here, and in the splendid students it produced. It is worth while to inquire concerning some of the causes that produced not only its past greatness, but also that of Paris and Prag.

In the first place, the students of Europe were free to attend any university and to migrate from one university to another. Of course they went wherever they were attracted. At Padua the vast number—at one time 6000—was divided into partially self-ruling divisions according to nations. Padua, like Paris, Prag, Oxford, or Leyden, was a world-university.

The success of a university in attracting students depended on the quality of learning to be found. The best of professors were sought out by Padua; its roll of teachers included men of the rank of Galileo and Vesalius. The faculty, like the body of students, was international. The great mathematician Belmondi was followed in succession by Peurbach, Müller (Regiomontanus), and Paul of Middelburg.

To-day Padua is a purely Italian university. The 3220 students are all Italians, except for 47 foreigners (of whom 9 are Austrians). The Dutch universities ceased to be more than national affairs because Latin ceased to be the international language of learning, and no one would learn Dutch in order to study in Holland. This cannot be the case with Padua, because Italian, like German or French, is a language worth learning. That students will learn a language in order to study in a foreign country is shown by the great numbers of foreigners who studied in Germany before the war. The cause must be sought elsewhere.

Careful inquiry fails to find a single professor of the highest international fame now here, whatever the national reputation may be. This is one of the reasons for the change in Padua.

Students may attend a university on account of itself, regardless of the professors. This is the main force for most universities to-day except in Germany. A man goes to Oxford or Harvard because it is Oxford or Harvard, and not because there may be a famous man in his particular line. This determines successfully the large body of undergraduates as in English universities, but there is no undergraduate instruction at Padua. The principle becomes unfavourable when applied to a *graduate* university, as seen most strikingly in Padua. Its students, mainly from the north of Italy, attend in order to get their degrees, and afterwards their places and appointments. They become good lawyers, doctors, engineers, etc., but they do not receive the training in research and the inspiration toward originality of the olden days. The reflex on the university as an institution of research is unfavourable; Padua to-day does not hold the highest rank as one of the producers of modern thought.

The history of Padua shows clearly the faults of a system that attempts to build on any other principles than those of free migration of students and the appointment of distinguished professors of creative minds.

This condition may be illustrated by an impression received in London. Although Padua has been specially famous for its medical teaching—Vesalius, Fallopius, Morgagni—and its distinguished student Harvey, it was impossible to find in any medical library in London an account of Padua, except Sir George Newman's interesting address to the students of St. Bartholomew's. This lack of interest corresponds to—or produces?—a reciprocal feeling on the part of the Italians. Most noticeable is the fact that most of the students can speak German, while very few know anything of English.

A most striking feature of the celebration was the large attendance of foreign delegates. The British delegation comprised Sir Archibald Garrod (Oxford) the chairman, Lord Dawson of Penn (Royal College of Physicians), Sir Humphrey Rolleston (Royal College of Surgeons), the Astronomer Royal, Sir Frank Dyson, (Royal Society), Prof. Conway (British Academy), Prof. Okey (Cambridge), Prof. Caton (Liverpool), Mr. D. G. Hogarth (London), Prof. H. H. Turner (London), Sir William Smith (London), Mr. Chaston Chapman (London), G. M. Trevelyan (London), Father Cortie (Stonyhurst), Dr. Seton (London), Dr. Scripture (Philological Society), Prof. Burnet (St. Andrews), Dr. Baird (Glasgow), Prof. Barger and Dr. H. R. F. Brown (Edinburgh), Sir George Smith, Prof.

MacWilliam and Prof. A. C. Baird (Aberdeen), Prof. Martin (Glasgow), Prof. Fitzgerald (Belfast), Prof. O'Rahilly and Prof. J. F. D'Alton (Cork), Sir Robert Woods and Mr. E. H. Alton (Dublin).

The Canadian delegation included Prof. Bieler (Montreal), Sir George Parkin (Fredericton), Mr. R. C. Archibald (Sackville), Dr. O. Klotz and Mr. E. Deville (Toronto), Dr. H. Ami (Ottawa). The university of Sydney sent Mr. C. MacLaurin. India was represented by Prof. Chatterji and Prof. Mallik of Calcutta.

At the solemn ceremony on May 15 the delegates were classified in groups. England, Scotland, Wales, Ireland, Canada, and Australia formed one group. France, Spain, and the South American States formed another group. Strange new States also appeared. One group comprised Esthonia, Latvia, Finland, Poland, etc. Germany had its independent place, while the countries of Asia were ably represented by Prof. Chatterji of Calcutta, who made a charming speech in English and Sanskrit.

Current Topics and Events.

FIVE fellows of the Royal Society are included in the list of honours conferred on the occasion of the King's birthday, namely, Dr. H. K. Anderson, master of Gonville and Caius College, Cambridge, Prof. W. M. Bayliss, professor of general physiology, University College, London, Prof. F. W. Keeble, Sherardian professor of botany, University of Oxford, Dr. T. R. Lyle, formerly professor of natural philosophy in the University of Melbourne, and Dr. E. J. Russell, director of the Rothamsted Experimental Station. Among other names we notice those of Sir B. G. A. Moynihan, professor of clinical surgery, University of Leeds, who has been made a baronet, Dr. J. Macpherson, professor of psychiatry, University of Sydney, and Dr. W. Thomson, lately registrar of the University of South Africa, who have received the honour of knighthood, and Mr. A. E. Kitson, director of Geological Survey, Gold Coast Colony, who has been made a Companion of the Order of St. Michael and St. George (C.M.G.).

REPORTS have appeared in the daily press of plagues of caterpillars defoliating oaks, particularly on the borders of Surrey and Hampshire. They have also been observed in the wooded country near St. Albans. Large numbers of the caterpillars, suspended by silken threads from the branches of the oaks, are a common feature of such infestations, and are often an annoyance to people walking along woodland roads. The insect primarily concerned is *Tortrix viridana*: the moth of this species is a small insect with pea-green fore-wings and smoky brownish hind-wings. During the end of this month it will appear in myriads throughout the countryside wherever the caterpillars have been abundant. Fortunately there is only one generation in the year and, once the moths appear, there will be no recurrence of the caterpillars during the same season, and the trees commence to shoot out fresh leaves. The effect of the defoliation naturally checks the growth of the trees to some extent for the time being, but is rarely more serious, and infestations of this kind are very common during hot dry weather.

WE notice with deep regret the announcement that Dr. W. H. R. Rivers, distinguished by his brilliant work in anthropology and psychology, died on June 4, at fifty-eight years of age.

IT is announced that Mr. C. T. Heycock, Goldsmiths' Reader in metallurgy at the University of Cambridge, has been appointed Prime Warden of the Goldsmiths' Company.

THE centenary of the death of René Just Haüy, "the father of crystallography," occurred on June 3. Haüy, who was of humble parentage, was born at Saint-Just-en-Chaussée, Oise, February 28, 1743. After great privations and extraordinary exertions, at the age of twenty-one he became a teacher in the College of Navarre in Paris. Here he began the study of botany. An accident, however, with a crystal of calcareous spar attracted him to the examination of minerals and led him to the discovery of the law of crystallisation. The happy issue of this was that he gained the favourable opinion of Daubenton and Laplace, and in 1783 was elected a member of the Academy of Sciences. Though as an ecclesiast he stood in some danger at the Revolution and was indeed committed to prison, his numerous friendships and the esteem in which he was held secured him from serious trouble. He afterwards became one of the first members of the National Institute, was secretary to the commission on weights and measures, lectured at the Ecole Normale, and held a chair at the Jardin des Plantes. Edward Stanley, the well-known Bishop of Norwich, when visiting the Jardin des Plantes in 1814, wrote: "Here as everywhere else the utmost liberality is shown to all, but to Englishmen particularly, your country is your passport. . . . Haüy, you know, is the first mineralogist in Europe and I never looked upon a more interesting being. When he entered the lecture room everyone rose out of respect, and well they might. He is 80 years of age apparently, with a most heavenly patriarchal countenance and silver hair . . . he looked like a man picked out of a crystal, and when he dies he ought to be reincarnated and placed in his own museum." Haüy's brother, Valentin, was the inventor of raised type for the blind, and in 1903 a monument to both of them was unveiled at Saint-Just. There is also a monument to the Abbé Haüy in Paris.

IN his presidential address at the anniversary meeting of the Royal Geographical Society on May 29, Sir F. Younghusband, the retiring president, dwelt briefly on the need for more intensive geographical examination of the homeland. The spadework of this form of exploration has of course been completed in topographical and geological surveys, faunas and floras and so forth, but the true geographical description is still far from complete. The

bare facts are not enough: it is necessary to be able to seize the essential characteristics of a country and, discarding unimportant details, to bring those essential characters together in a connected whole, in order to give a clear and definite impression that will readily implant itself upon the mind. This work, Sir F. Younghusband said, does not involve the problem of transport: it can be done far better on foot, and the homeland explorer does not even require the qualification of youth. "We [must] gather to us men with eyes to see, and hearts to feel, and heads to think, who will be fired with enthusiasm to explore round about their own homes and then come here and describe to us what they have seen."

THE March number of the *Tropical Agriculturist* contains an account of the work at the Royal Botanic Gardens, Peradeniya, Ceylon, the centenary of the establishment of which occurs this year. In 1810 Sir Joseph Banks drew up a plan for a botanic garden which was established two years later at Colombo. In 1822 the work was transferred to Peradeniya, near Kandy, the site of the late Kandian king's garden, under the superintendence of Alexander Moon. The first plan of the garden, which was 147 acres in extent, is now in the Library of the Royal Horticultural Society in London. Work of development, begun in earnest in 1844, with the appointment of George Gardner, received a temporary check on Gardner's death in 1849, but in the next thirty years, under the superintendence of G. H. K. Thwaites, the gardens attained considerable fame. Thwaites was succeeded in 1880 by Henry Trimen (1880–1896) who, continuing Thwaites' investigation of the flora of the island, brought out the well-known "Handbook of the Flora of Ceylon." J. C. Willis succeeded Trimen, but retired in 1911, when the gardens were placed under the newly constituted Department of Agriculture. Peradeniya has played an important part in the agricultural development of the colony in connection with the introduction and acclimatisation of plants of ornamental and economic value. The chief interest was coffee until the industry was ruined by the coffee-leaf disease, when it was replaced by cinchona and subsequently tea. The rubber industry of the East owes much to the work in Ceylon, where seedlings were transferred from Kew in 1876; in 1906 the first of the World's Rubber Exhibitions was held in the Peradeniya Gardens. In 1887 a small botanical laboratory was fitted up in the gardens, and many British and Continental botanists have taken advantage of the facilities thus afforded for the study of botany in the tropics. In 1900 this was replaced by a larger well-equipped building.

THE third annual report of the Governors of the Imperial Mineral Resources Bureau, which has recently been issued, contains much interesting information. It is gratifying to see that at last a serious attempt is being made to adopt a unified system of mineral statistics applicable to the whole of the British Empire. This reform is long overdue, and it is to be sincerely hoped that the present effort will meet with success. The greater part of the report is devoted to a general review of the mineral industry of the British Empire and foreign countries for the year 1921, and the importance to the industry of such a comprehensive review at so relatively early a date can scarcely be overestimated. Even if the figures given are only approximately correct, they will serve as a trustworthy guide to the general trend of the industry. Unfortunately the picture is a very gloomy one, being a practically uniform chronicle of world-wide depression; almost the only exception is to be found in the coal production of Germany, which shows an appreciable improvement on that for 1920, and in the words of the report, "Considering the loss of the coal production of the Saar, the approach of Germany's fuel production in 1921 to the pre-war figures is significant."

A LECTURE on the mechanical construction of the microscope from a historical point of view, given by Prof. Alan Pollard before the Optical Society on April 27, dealt with the evolution of the instrument from the earliest times until about the middle of the nineteenth century. Prof. Pollard divided his subject into two main periods—the non-achromatic, in which the early history of the single lens or simple microscope was dealt with, and the achromatic. The mechanical details of outstanding historical compound instruments of these two periods which marked the progress of mechanical construction to the modern compound microscope, were described. Many famous instruments of the first period, such as John Marshall's "New Invented Double Microscope" of 1693, Culpeper's "Double Reflecting Microscope" of 1735, Cuff's "Double Constructed Microscope" of 1744, B. Martin's simple and compound instruments of 1765, Bleuler's "Universal" of 1788, Jones' "Most Improved" of 1798, by Dollond, Gould's "Pocket Microscope" of 1828, by Cary, as well as Lister's famous compound microscope, by James Smith in 1826, which marked the opening of the second period in this country, were set up with histological specimens so that their mechanical and optical performances could be compared. In addition, early catoptric instruments were shown, including Amici's reflecting microscope, made for Dr. Wollaston in 1830. The development in particular of the modern English limb from the Lister and Jackson designs, and the so-called continental limb from the early forms of Oberheuser and Nachet, was traced and described.

THE gold medal of the Linnean Society of London, which is given in alternative years to a botanist and a zoologist, was this year awarded to Prof. E. B. Poulton at the anniversary meeting on May 24. In making the presentation, the president, Dr. A. Smith Woodward, referred to Prof. Poulton's long labours in entomology, and his keepership of the Hope Collection at Oxford, transformed by him into a great museum, illustrative of variation, mimicry, and evolution. Prof. Poulton, in replying, mentioned the fact that half a century had elapsed since his matriculation at Oxford. At the same meeting of the Society the following officers were elected: *President:* Dr. A. Smith Woodward; *Treasurer:* Mr. Horace W.

Monckton; *Secretaries:* Dr. B. Daydon Jackson, Prof. E. S. Goodrich, and Dr. A. B. Rendle; *Members of Council:* Prof. Margaret Benson, Dr. G. P. Bidder, Mr. E. T. Browne, Dr. W. T. Calman, Prof. F. E. Fritch, Prof. E. S. Goodrich, Dame Helen Gwynne-Vaughan, Sir Sidney F. Harmer, Dr. Arthur W. Hill, Dr. B. Daydon Jackson, Mr. Gerald W. E. Loder, Mr. Horace W. Monckton, Mr. Frank A. Potts, Capt. John Ramsbottom, Dr. A. B. Rendle, Baron Rothschild, Dr. E. J. Salisbury, Mr. Charles Edward Salmon, Mr. Thomas Archibald Sprague, and Dr. A. Smith Woodward. Among the Vice-Presidents nominated for the present session appears the name of Dame Helen Gwynne-Vaughan, the first woman to attain that dignity, although it is nearly eighteen years since women were eligible for the fellowship, and for the last fifteen years they have been elected to the Council.

THE Council of the Institution of Electrical Engineers has made the following awards for papers accepted during the session 1921–22: the Institution Premium to Mr. J. G. Hill, the Ayrton Premium to Mr. L. H. A. Carr, the Duddell Premium to Mr. T. L. Eckersley, the Fahie Premium to Mr. E. S. Byng, the John Hopkinson Premium to Mr. F. P. Whitaker, the Kelvin Premium to Mr. R. Torikai, the Paris Premium to Mr. J. A. Kuyser, extra premiums to Mr. J. Anderson, Mr. F. J. Teago, and Mr. W. Wilson, wireless premiums to Mr. E. B. Moullin and Mr. L. B. Turner, and Mr. C. S. Franklin; and the Willans Premium, which is awarded triennially alternately by the Institution and the Institution of Mechanical Engineers, to Mr. K. Baumann.

THE British Non-Ferrous Metals Research Association, 71 Temple Row, Birmingham, has carried out an extensive research on the influence of gases on high-grade brass. A further investigation is now being started by the Association at the Research Department, Woolwich, in which the support of the Engineering Co-ordinating Board of the Department of Scientific and Industrial Research has been secured. The prime object of the present work is to study the conditions necessary for securing both surface and internal soundness of strip brass ingots such as are required for cold rolled sheet metal. The investigation should also throw light on other types of casting in non-ferrous alloys and should be of interest to a wide circle of manufacturers in the metal and engineering trades. Dr. Harold Moore and Mr. B. Genders will have charge of the research, which will be conducted partly in the works of members of the Association and partly in the Woolwich laboratories.

BEFORE the war the United States did not undertake the manufacture of optical glass; thus the disc for the 100-inch at Mt. Wilson was made at St. Gobain in France. The exigencies of war, however, made home-manufacture necessary, much help being given by the geophysical laboratory at Washington. The work was at first limited to the small lenses needed for military purposes, but after the Armistice it was greatly extended, and electric furnaces were constructed for annealing the glass, the rate of cooling being carefully controlled. In an article in *Popular Astronomy* of May, D. E. Sharp states that a 40-inch disc for a reflector for the Steward Observatory, University of Arizona, has now been completed by the Spencer Lens Co., Hamburg, N.Y. The glass employed has a low coefficient of expansion, and it is hoped that changes of figure due to change of temperature will thus be minimised.

A BRONZE medal to be designated the Faraday Medal of the Institution of Electrical Engineers will commemorate the fiftieth anniversary of the first Ordinary Meeting of the Society of Telegraph Engineers (now the Institution of Electrical Engineers). The award may be made by the Council not more frequently than once a year, either for notable scientific or industrial achievement in electrical engineering or for conspicuous service rendered to the advancement of electrical science, without restriction as regards nationality, country of residence, or membership of the Institution.

INVITATIONS have been issued by the Lawes Agricultural Trust Committee (Chairman, Lord Bledisloe) to inspect the experimental fields and laboratories of the Rothamsted Experimental Station, Harpenden, on Wednesday, June 14, when the Minister of Agriculture (The Right Hon. Sir Arthur Griffith-Boscawen) and the Parliamentary Secretary (the Earl of Ancaster) will be present.

THE seventy-seventh general meeting of the Institution of Mining Engineers will be held on June 20–22 at Sheffield. A preliminary programme has been issued, which provides for papers and discussions on stainless steels, rock temperatures in coal-measures, coal-mining methods and apparatus, and the absorption of carbon monoxide by the blood. A number of visits to works and collieries in the neighbourhood have also been arranged.

A PUBLIC meeting of the National Union of Scientific Workers will be held in the Botanical Theatre, University College, Gower Street, London, on Thursday, June 15, at 5.30, when an address will be given by Mr. F. W. Sanderson, Headmaster of Oundle, on "The Duty and Service of Science in the New Era." The chair will be taken by Mr. H. G. Wells. Admission will be free.

IT is announced in the *Chemiker Zeitung* of May 18 that Prof. Duparc of Geneva has, at the invitation of the Soviet Government, undertaken the organisation of the platinum industry of Russia.

THE movement for "birth control" has now assumed considerable proportions, and the Malthusian League, which numbers many persons of eminence in medicine, science, and literature among its vice-presidents, issues monthly the *New Generation*, a publication devoted to this subject and to problems of population. The "Mothers' Clinic," for information and advice on the subject, has been established and is open daily, and issues monthly the *Birth Control News*, which "intends to present to those who desire to see them shorn of the ephemeral, the real problems facing national and international statesmanship to-day."

Research Items.

The Sacred Herakleopolite Nome Tree.—In *Ancient Egypt* (Part 1, 1922), Dr. F. F. Bruijning concludes his interesting paper on the sacred tree of the Egyptian Herakleopolite Nome. From numerous representations of this famous tree on the monuments, he reaches the conclusion that it may be identified with the wine-palm, *Raphia monbuttorum*, which has since then retreated southward, keeping its place longest where the special conditions for its growth, a warm, damp air and soil, as in the oases, were favourable. Most of the so-called "artichokes" represented among the funeral offerings undoubtedly represent the palm-cabbage, and older interpretations, such as the theory that they represent pine-cones, must be set aside. A clear distinction must be drawn between palm-wine, obtained from the sap of various species, drawn by incisions in the spadix or head, or by cutting off the spadix, and date-wine in which, as with other fruits, the ripe fruit is mashed, pressed, or boiled, and then fermented.

The Osage Tribe of American Indians.—The Bureau of American Ethnology in its thirty-sixth Annual Report, 1914–15, publishes a fine, illustrated monograph on the Osage tribe by Mr. F. la Flesche. Marquette first visited them in 1673, and thus a trading relationship was established with Spanish and French merchants. In 1806 began the crisis in their history, by which they gradually relinquished their territory to the United States, and in 1825 they gave up their ancient home and removed to a reservation in Kansas. Their present quarters are in Osage County, Oklahoma, where they removed in 1872. They are rapidly, as a tribe, approaching extinction, not by death but by absorption by the whites, and only a small minority are now of pure blood. They belong to the great Siouan linguistic family, their nearest kindred tribes being the Omaha, Ponca, Quapaw, and Kaw. The volume contains, both in the tribal dialect and an English translation, a full account of their tribal rites—the Rite of the Chiefs, which records their traditions in a cryptic form, and the Hearing of the Sayings of the Ancient Men. They were accustomed to appeal daily to Wakonda for a long and healthful life. "Therefore at dawn, when they saw the reddened sky signalling the approach of the sun, men, women, and children stood in the doors of their houses and uttered their cry for divine help: as the sun reached mid-heaven they repeated their prayer: and their supplications again arose as the sun touched the western horizon."

Bacteria associated with Rice and other Cereals.—Starch is prepared from tubers and cereals, and of these rice probably holds the first place as a source of starch. The raw material is washed, steeped, and ground with water, so that the starch separates from other constituents of the grain, and the milky suspension is allowed to stand in tanks in which the starch is deposited. Fermentation due to bacteria is liable to occur, particularly during steeping and settlement, and may cause serious loss. The chief source of bacterial infection is the grain itself. It is found that "polished" rice carries more bacteria than "unpolished" (*i.e.* unhusked) rice, due apparently to the removal with the protective epidermis of the grain of an alkaloidal substance which has antiseptic properties. When not required for seed the grain may be sterilised by means of sulphur dioxide. Ordinary "paddy," rice grain as it comes from the fields, carries sporing bacilli which are capable of fermenting the starch with the production of acetone and butyl alcohol—as much as 8-9 per cent. of acetone on the weight of rice taken being obtained (G. J. Fowler and Dhiresh Zobhan Sen, *Journ. Indian Inst. of Science*, Vol. 4, Pt. VIII., p. 119).

Migration Instinct in Birds.—Mrs. C. D. Langworthy of Claygate, Surrey, raises the question of the migration of young cuckoos as an example of "inherited memory." The adult cuckoos, being free from family cares, emigrate very early and have all left the country some weeks before the young ones, which they have never seen, are ready for the journey. The young must thus find their way unaided. There is no evidence that the foster-parents' example plays any part; indeed the latter are frequently birds of sedentary habit. A similar phenomenon also takes place in the case of many other migrants, such as the starling, for example, but with the order reversed; the young migrate separately when only a few weeks old, the adults following later after completing their autumn moult. These cases are scarcely easier to explain than that of the young cuckoos, for it is difficult to imagine anything equivalent to theoretical instruction beforehand. Migration is a very regular phenomenon, occurring year after year according to the same plan; much of it, too, takes place before the need has become really apparent, and thus it cannot be explained simply as the result of immediate stimuli and of the pressure of external circumstances. It is therefore difficult to escape the conclusion, not only that the migratory habit is an inherited instinct, but that some foreknowledge of the journey to be performed is in some way inborn.

New Dinosaur from New Mexico.—Mr. C. W. Gilmore describes "A new Sauropod Dinosaur [*Alamosaurus sanjuanensis*, n. gen. et n. sp.] from the Ojo Alamo formation of New Mexico" ("Smithsonian Miscellaneous Collections," vol. lxxii., No. 14). The remains so far recovered consist of a left scapula and a right ischium, both in a good state of preservation. The great importance of these particular bones lies in the fact that the remains of sauropodous dinosaurs have not previously been known to occur above the Lower Cretaceous in North America, so that the extension of their geological range into the Upper Cretaceous is of the greatest palæontological and geological interest. Much doubt attaches, in Mr. Gilmore's opinion, to the proper identification, or exact geological position, of the reported finds in other parts of the world of sauropod remains of Cenomanian age or later, although such dinosaurs doubtless continued to exist until after the Cenomanian and even into the Danian.

New Surveys in Arabia.—The *Geographical Journal* for May contains a new map of northern Arabia prepared by the Geographical Section of the General Staff. The map incorporates the work of the late Capt. W. H. I. Shakespear, especially his great journey across Arabia in 1914 from Koweit on the Persian Gulf to the Egyptian outpost of Kuntilla in Sinai. These observations were utilised during the war in the construction of the 1/M map of Arabia, from which the present map is reduced to the scale of 1/1·5 M. Mr. D. Carruthers, in an article accompanying the map, points out that Capt. Shakespear's trans-Arabian journey covered about 1200 miles of unknown country and that for the whole distance, 1810 miles, he kept up a continuous route traverse, checked at intervals by observations for latitude.

Hypsometric readings for altitude were also taken. The new work included the first complete traverse of the Wadi er Rumma in its lower course, el Batin; the region southward to Zilfi and thence to Riyadh; much new detail between Riyadh and Buraida; and a completely new route from Buraida to Jauf and between Jauf and the Wadi Araba on the frontier of southern Palestine.

DEATH VALLEY.—An article is given in the U.S. *Monthly Weather Review* of January last by Mr. Andrew H. Palmer of the U.S. Weather Bureau on the weather at the Bureau's substation at Greenland Ranch in Death Valley, California. The valley extends from north to south for a distance of about 100 miles, and lies between high mountain ranges. The width varies from two to eight miles, and it is the deepest depression in the United States. The instrument shelter is 178 feet below sea level, and the maximum and minimum thermometers with the thermometer screen, as well as the 8-inch rain gauge, are lent by the Weather Bureau. Unbroken weather records are now available for more than ten years. Nearly every summer the highest temperatures observed in the United States occur in Death Valley. The extreme maximum temperatures recorded during the last eleven years, to 1921, range from 134° F. in 1913 to 120° in 1912; the extreme of 134° F. observed on July 10, 1913, is said to be the highest natural air temperature ever recorded on the earth's surface by means of a tested standard thermometer exposed in a standard louvered screen. Temperatures of 100° or higher occur almost daily during June, July, and August; in July 1917 the mean temperature was 107°·2. Not infrequently six consecutive months have passed without measurable rain. In 1917 the total rainfall was less than half an inch, and the annual average precipitation is less than two inches. There is said to be some sunshine during practically every day in the year. Four crops of alfalfa are gathered each year.

GEOLOGICAL RESEARCH AND EDUCATION IN CONNECTICUT.—The Connecticut State Geological and Natural History Survey has collected its bulletins issued between 1915 and 1920 as volume vi. of its publications, which are distributed gratuitously "to public libraries, colleges, and scientific institutions, and to scientific men, teachers, and others who require particular bulletins for their work, especially to those who are citizens of Connecticut." The present thick but easily opened volume contains over 1100 pages, with abundant plates, maps, and other illustrations. Geologists will welcome Prof. R. S. Lull's treatise on "Triassic Life of the Connecticut Valley," as a record of life and conditions on the land at the opening of Mesozoic times. We are present, as it were, at the rise of the dinosaurs, and the original restorations serve admirably to impress the characters of these dominant forms on the minds of every teacher in the schools. Podokesaurus, recently discovered and described by Miss M. Talbot, is fully discussed and illustrated, for comparison with its Upper Jurassic ally, Compsognathus. A complete review is given of the footprints that abound in the shales and sandstones, especially in the upper beds of the system; some may represent amphibia, but the associated bones show that many must be ascribed to dinosaurs. Bulletin 26, by Prof. V. W. Kunkel, describes the existing amphipod and isopod Crustacea of the State, and Dr. W. C. Britton gives a list of the insects, occupying 400 pages.

THE FLOTATION OF CONTINENTS.—Prof. Wegener's views on continental movement were stated in a recent review (NATURE, February 16, p. 202) of the second edition of his work on "Die Entstehung der Kontinente und Ozeane." His daring suggestions were formulated in 1912, and we cannot quite dismiss them as Prof. L. Kober does, by saying "im Bau der Erde hat die Theorie der grossen Kontinentalverschiebungen keine Stütze." However much we may doubt the horizontal movement of masses of "sal" across uncrumpled "sima" areas, the proposition that has arisen in the mind of a geographer can be met only by argument on the part of the geologist. Prof. Wegener has contributed to *Discovery* (vol. iii. p. 114, May 1922) a lucid summary of his conceptions, accompanied by maps, showing, among other wonders, the transference of the Deccan to the antarctic region in Carboniferous times. A polar ice-cap, spreading across the conference of continents here cunningly arranged, would not explain the movement of an ice-sheet from north to south in southern Africa. Mr. A. L. du Toit, however, in two notable papers dealing with former land-connections and the glaciation of South Africa (*S. African Journ. Sci.*, vol. xviii., Dec. 1921, and Trans. Geol. Soc. S. Africa, vol. xxiv. p. 188, 1921) welcomes the new hypothesis. His map of Gondwanaland as promoted by flotation, with its arrows showing the direction of ice-movements, seems to require a snow-dome near the south of Madagascar, and a separate glaciation of Australia by the polar cap. We should like to study Prof. Wegener's explanation of the arid climates of the Trias, and of the cold conditions prevalent over the whole earth in the latest glacial epoch. For him, New Zealand (see NATURE, vol. 109, p. 657) has been left behind by the westward drifting of Australia, and his "Old Quaternary" map does not explain its glaciation on geographic grounds. The Carboniferous map shows a general submergence of Eurasia, so that his seeming repudiation of vertical movements in accounting for changes on the earth's surface may be something like the waving of a red flag at the head of an orderly industrial procession. We shall hope for a thorough discussion of his proposals in the light of what is known as to marine transgressions across the continents.

EFFECT OF LIGHT ON MUSEUM SPECIMENS.—The *Museums Journal* for April contains a detailed account by the Director of the Natural History Museum of the careful experiments that he has conducted there for many years, with the help of the late W. G. Ridewood, on the fading of colour in museum specimens. Direct sunlight is, says Sir Sidney Harmer, far more injurious to colours than any other method of illumination, and diffused daylight appears to produce more fading than any form of electric light used. This statement applies to oil-colours as well as to water-colours and the colours of various animal coverings, and suggests caution to those who, on the advice of Sir M. H. Spielmann, would put their oil-paintings in a blaze of sunlight. The various glasses designed by Crookes and others to cut off the more deleterious rays were not found sufficiently satisfactory to warrant the expense of their installation. The practical conclusion of the whole matter is that direct sunlight should be avoided at all costs, and that even diffused daylight should be shut out at all hours when exhibition galleries are closed to the public. At other times the light, if at all bright, should be moderated by yellow blinds. A gallery lighted entirely by electric light, preferably in the form of half-watt lamps, would have great advantages. The paper is one that should be studied by all directors of museums, including art galleries.

The International Union of Geodesy and Geophysics.

THE first meeting of the General Assembly of this Union, which was held at Rome at the beginning of May, was attended by delegates from the fourteen countries which at present form the Union, and also by a number of representatives from several other countries which, though belonging to the International Research Council, have not yet joined the Union.

The Union, which was constituted at Brussels in 1919, has for its object the promotion of the study of geodetic and geophysical problems and of international co-operation in research. It covers not only the ground with which the former International Associations of Geodesy and Seismology dealt, but its sections provide for similar activities in meteorology, terrestrial magnetism, physical oceanography, vulcanology, and scientific hydrology.

The meetings of the Union and its constituent sections were held in the rooms of the Reale Accademia dei Lincei on May 3–10, and were preceded by an official reception of the delegates and members of the Astronomical and of the Geodetic and Geophysical Unions by the Minister of Public Instruction at the Capitol, at which His Majesty the King of Italy was present.

As the meeting in Brussels in 1919 was held for the special purpose of constituting the International Research Council and the Unions which are related to it, no scientific discussions took place there; since then the organisation of the Union and its sections has entailed a considerable amount of work. At Rome, therefore, each section had to prepare its plans for international work, and in the case of geodesy and seismology, to review the progress which had been made since the last international meeting. In all sections good progress was made, and plans were adopted for the work which will be put in hand in the period which will elapse before the next meeting of the Union in 1924.

In geodesy the programme was a heavy one, for ten years have elapsed since the last meeting of the International Geodetic Association at Hamburg in 1912. Very interesting summaries of the work which it has been possible to carry out during this period were presented by the delegates of the various countries, and these will be published in the report of the section of geodesy. It had been suggested at Brussels that the study of variation of latitude should be confided to the Union of Astronomy instead of to that of Geodesy. The question was fully discussed at Rome by a committee representing the two Unions, and it was decided that the subject should remain with the Section of Geodesy, a joint committee of geodesists and astronomers, with Prof. Kimura as chairman, being appointed to direct the work.

To carry out the decisions of the Section, and to deal with any matters which might arise, an executive committee was appointed, as well as a General Committee, on which each country adhering to the Section will be represented. The General Committee will be consulted on matters which go beyond the powers of the executive committee in the interval between two meetings.

For each principal branch of technical work a reporter was appointed who will prepare a statement on the progress made in it for the periodical conferences, and will also facilitate co-ordination between workers in different countries. Mr. W. Bowie of the U.S. Coast and Geodetic Survey continues as president, with Lieut.-Colonel G. Perrier of the French Geodetic Service as secretary.

As the International Seismology Association was still in being at the time of the Conference at Brussels, no change could then be made, and the Section of Seismology was only constituted at Rome, when Prof. H. H. Turner, of Oxford, was elected president, with Prof. Rothé of Strasbourg as secretary. The subjects for discussion included the study of microseisms, the depth focus of earthquakes, and proposals for studying explosion phenomena and wave propagation. Much work was done in organising the Section, and in planning work to be undertaken before its next meeting. The work now being done at Oxford and at Strasbourg is to be carried on, and to this the Section will give such assistance as it can.

Meteorology is represented in the Union by a Section which is a new organisation in so far as it does not replace a pre-war institution of a corresponding character. Its relations to the International Meteorological Committee, which has been in existence for many years, came up for discussion; this committee consists of a certain number of Directors of meteorological services, and at its periodical conferences, such as that which met at Paris in 1919, many questions are discussed which arise from the relations existing between the meteorological services of different countries. It was agreed that, in addition to questions of this character, there were many investigations for which international co-operation was essential, which directors of meteorological services might find it difficult to include in their work. Such investigations might with advantage be initiated by the Section, and at Rome plans were discussed for work of this character. The composition of the atmosphere at high altitudes, and the physical conditions prevailing in the stratosphere, were specially considered as being subjects in which an increase of our knowledge is highly desirable, and plans for work upon them were adopted. It is clear that the two organisations would in no way overlap, but that the work of each would usefully supplement that of the other. Sir Napier Shaw was elected president of the Section, with Prof. Eredia of the Italian Meteorological Service as secretary.

The Section of Terrestrial Magnetism and Electricity was fully occupied with a long programme dealing largely with methods of observation and with the reduction of results; no particular method of scale-value determination was agreed upon in view of the diverse types of instruments in use. The selection of one observatory in each country which should take part in the international comparison of instruments was advocated, and a committee was appointed to formulate a scheme for such intercomparisons. Other committees were formed to deal with polar-light observations, with earth currents, and observational work in atmospheric electricity. Dr. C. Chree was elected president, with Dr. L. A. Bauer as secretary.

The Section of Physical Oceanography had held one meeting in Paris in January 1920, at which committees were nominated to facilitate co-operation in oceanographical work in the Atlantic, in the Pacific, and in the Mediterranean. At Rome these were confirmed, and the recommendations of the Tidal Committee for improving the collection of tidal information and data, and for attaining uniformity in their reduction, were adopted. A proposal to provide, by means of a committee or a section, for the co-ordination of biological work in oceanography with the physical work of the Section, was adjourned until the next conference in order that opinions from various countries might be obtained. H.S.H. the Prince of Monaco continues as president, with

Prof. G. Magrini of Venice as secretary. The publication of a periodical which would deal specially with the bibliography of the subject was also approved.

In the Section of Vulcanology, which was formally constituted at the Conference, M. Lacroix was elected president, with Prof. Malladra and Prof. G. Platania as secretaries. Proposals for the classification of volcanic phenomena, and for the recording of volcanic outbursts, were adopted, as also were those for the investigation of the thermal gradient in certain areas.

In more than one quarter the proposal had been made that an additional section should be formed to deal with the scientific problems which arise in various hydrological investigations, such as river-gauging, lake phenomena including seiches, run-off and evaporation, transport of material in suspension and in solution, glacier movement, etc. A committee examined the matter carefully and reported in favour of forming a Section of Scientific Hydrology. The recommendation was adopted by the General Assembly, which nominated Mr. B. H. Wade of the Physical Department, Cairo, as president, and Prof. G. Magrini as secretary.

The General Assembly of the Union re-elected M. Ch. Lallemand to be president, Colonel H. Lyons remaining secretary-general. It was resolved that countries belonging to the International Research Council which had formerly been members of the International Geodetic Association might join the Union and the Section of Geodesy, without subscribing to the other sections, if they so desired. It was further resolved that the next meeting of the Union should be held in 1924, and an invitation from the Spanish Government to hold the next Conference of the Union at Madrid was accepted. It is understood that the probable date will be the latter part of September.

Arrangements were made for members to visit, after the Conference, the Central Institute for Marine Biology at Messina, and the Marine Research ship *Marsigli*. For those interested in vulcanology visits to Stromboli, Catania, Etna, and Naples were arranged, while at Florence the Observatory and the various scientific institutes and museums were open to the members, to whom the municipality gave a reception at the Palazzo Vecchio.

The proceedings in each Section will be published in due course by the Executive Committee of the Section.

H. G. L.

Annual Conference of Universities.

ALL the Universities of Great Britain and Ireland were represented at the Conference which met at University College, London, on May 13. Each University had been asked to send three representatives in addition to its executive Head, and each University College to send its Principal and one other representative. Of the Vice-Chancellors or Principals three only were unable to attend. Sir Donald MacAlister (Glasgow), chairman of the Standing Committee of Vice-Chancellors, presided. Mr. Fisher, President of the Board of Education, was present and took part in the discussions.

The subject of the urgent need for the provision of enlarged opportunities for advanced study and research was introduced by Principal Irvine (St. Andrews), who pleaded that the Universities should not leave original research to the solitary worker, but should place facilities for research in the way of every one naturally equipped with the spirit of inquiry. It is impossible to summarise Principal Irvine's address, but the main contention was that training in research should be in the hands of mature investigators who should be relieved of all routine and administrative work. Principal Sibly (Swansea) said that the importance of the applications of science had become so clear to the public during the war that technological studies were now greatly favoured and the opportunities of prosecuting pure science were actually narrower than they were ten years ago. Sir Richard Lodge (Edinburgh) sounded a warning that training may be overdone. Many a research worker, left to himself, has learned more from his blunders than from his supervisor's advice. He emphasised the value of the Institute of Historical Research, which should, he thought, have a semi-federal character and be regarded, not as the possession of a single University, but in some degree, as common to all, since all historians must come to London to consult the documents which they need for the purposes of research. In this he was supported by Principal Grant Robertson (Birmingham).

The need for an increase in residential accommodation for students was urged by Sir Michael Sadler (Leeds), who stated that the desire for college life had recently been greatly strengthened in the newer Universities. In part it has been met. The increase in accommodation during the past year amounted to no less than 17 per cent. But very much more is needed. Women students equally with men recognise that, unless they share in the corporate social life of a Hall of Residence, they do not reap the full benefit of a University career. A very valuable discussion of the details of organisation and management followed, in which various speakers, drawing upon their own administrative experience, stated, amongst other things, that they had found that from 65 to 75 students is the economical unit (Principal Childs would place the number somewhat higher), that the Halls (the term "Hostel" was generally disapproved) should be independent of the Universities, that younger members of the staff should be encouraged to live in the Halls, that discipline and even management must be largely in the hands of the students, and that students must have some degree of privacy. It was agreed that no teaching should be given in the Halls. The most desirable situation for Halls in industrial towns was also discussed. For health and recreation they should be grouped around the playing-fields. This means that the residential quarters will be at a distance from the University buildings. Danger will arise, in consequence, of a division of the University into two groups of students with different centres of patriotism. This can be met by the provision in the immediate neighbourhood of the University of commodious "Union" buildings, and by encouraging the students who live at home or in lodgings to found a "Hall" with a warden and elected officers.

Dr. L. R. Farnell (Oxford), in introducing the subject of specialisation in certain subjects of study by certain Universities, argued that the time has passed when every University can attempt to foster all the shoots which are constantly being thrust forth by the tree of knowledge. Some flourish only where local conditions are favourable, others are so esoteric that a few centres will satisfy the needs of all their votaries. Mr. Fisher endorsed the views of the Vice-Chancellor of Oxford. When the Govern-

ment gave their support to the Universities Bureau they did so with the view of inducing the Universities to take counsel together, to encourage co-operation, and to enable overlapping to be avoided, without that external interference which they all deprecated. The development of applied science has reached dimensions which make it imperative, if the nation as a whole is to advance, that much more consideration than has hitherto been thought necessary should be given to the distribution of studies. The more conference there is between those responsible for University policy in England and Scotland the better it will be, especially if we are to look forward to a certain number of lean years. He suggested that the Vice-Chancellors' Committee be asked to consider (1) what new specialist departments, requiring for their development new endowments, may be appropriate to particular Universities; (2) whether existing trust funds in particular Universities could be applied to better uses within those Universities; and (3) whether the statutes of the different Universities could be so altered as to facilitate migration, in order that students may obtain specialist teaching. The chairman promised to report Mr. Fisher's proposals for inquiry to the next meeting of the Vice-Chancellors' Committee.

The subject of the Organisation of Adult Education as an integral part of the work of the Universities was introduced by Sir Henry A. Miers (Manchester), chairman of the Conjoint Committee of the Universities and the Workers' Educational Association, who pointed out the desirability of bringing into co-operation many bodies in addition to the one in which he is especially interested. He and subsequent speakers emphasised the importance of restricting the expression "Higher Education" to its legitimate sense as such a standard of education as only Universities can provide. There is a real danger of the Universities, moved by sympathy for those who have done great things in the way of making good early deficiencies, accepting as "higher," education which is not of a University type. There is also danger of trade-unions imagining that they can employ imperfectly trained persons as instructors. Mr. R. Peers, head of the Department of Extra-mural Teaching, gave a very interesting account of the organisation of Adult Education undertaken by the University College of Nottingham.

The Centenary of the Royal Astronomical Society.

THE actual date of the centenary of this Society was February 1920. Prof. A. Fowler, who was then president, delivered an appropriate address on that occasion, recapitulating the circumstances of the origin and early history of the Society. It was felt, however, that the conditions of foreign travel were still too difficult to render the occasion suitable for a full celebration of the event. Early in the present year it was thought that it would be well to take advantage of the presence of a large number of astronomers in Rome, at the meeting of the International Astronomical Union, many of whom, it was hoped, would be able to visit London on their way home. The end of May was therefore chosen as the date for the celebration, which was attended by a considerable number of associates.

The celebration opened with a conversazione on May 29, for which the Royal Society kindly lent its rooms; more than 300 guests were present; the exhibits included a collection of Newton relics, a number of ancient astronomical and mathematical books, calculating machines, and a model illustrating the probability curve. Five short lectures were delivered in the meeting room, on Sunspots, Planets, Comets, Instruments, and an anecdotal lecture on some former Fellows.

The morning of May 30 was devoted to addresses on the history of the Society. Prof. Eddington, the president, read the loyal message which had been sent to the King, as Patron of the Society, also his gracious reply, of which the following is an extract:

"You can rest assured that the King watches with interest and admiration the patient, diligent, and unobtrusive manner in which the Fellows of the Society conduct their unremitting research, in the hope that they may, by piercing the hidden mysteries of the skies, add step by step to the store of scientific knowledge, and thus contribute so much that is essential to the progress of mankind on land and sea."

He then read messages from many of the absent associates, which spoke of the great work that the Society had done for astronomy during the century of its existence, and expressed confident hope that its future would be equally fruitful. Similar messages of congratulation were received from many scientific societies.

The inaugural address by the president was a general survey of the progress of astronomy during the century; he suggested the following six events as marking definite steps of progress: 1839, the first stellar parallaxes were measured by Bessel and Henderson; 1846, Neptune was discovered as a result of the solution of the problem of inverse perturbations by Adams and Le Verier; 1854–58, the commencement of astronomical spectroscopy by Huggins and Lockyer; 1882–87, the beginning of stellar photography; 1904, Kapteyn's discovery of the two star-streams, which led to the beginning of stellar dynamics; 1920, the first direct measure of a star's diameter, by the Mt. Wilson interferometer. On the whole the twentieth century has been marked by the shift of the main interest from the solar to the stellar system. The former, however, is not entirely neglected; Prof. Eddington instanced planetary photography, the discovery of new faint satellites, and the Trojan group of asteroids, Einstein's explanation of the motion of Mercury's perihelion, the work of Taylor and Jeffreys on tidal friction in the Irish Sea, and Jeans's work on the cosmogony of the solar system.

Dr. Dreyer then delivered an address on the history of the Society, referring to the low ebb that astronomy and mathematics had reached in England before its foundation. One reason given was the continuance of the clumsy fluctional notation, which had already been superseded on the continent. One method attempted for encouraging research did not meet with great success; this was the offer of prizes for the solution of certain problems; it was noted that the prize offered for the mathematical treatment of the Saturnian satellite system met with a reply 80 years later, when Dr. Hermann Struve was awarded the Gold Medal for his work on Saturn's system. Reform of the Nautical Almanac was another work in which the Society interested itself. It awarded the Gold Medal in 1830 to Encke for his improved Berliner Jahrbuch; in 1834 our own Almanac followed suit. In 1835 the Society was given rooms in Somerset House, where it remained till it occupied its present abode in 1874. Allusion was made to the absorption of the Spitalfields Mathematical Society in 1845; it enabled them to claim

that in a sense they were keeping their second centenary, since that Society went back to 1717. Most of their old mathematical books were acquired from that Society. Allusion was made to the invaluable services of two assistant secretaries, Mr. Williams, known for his studies of Chinese comet records, and Mr. W. H. Wesley, who had now held that office for 47 years; much to their regret, illness prevented him from taking part in the centenary celebration. Allusion was made to the Society being consulted on the question of the remeasurement of the fundamental arcs in the British survey, and to the granting of the new charter in 1915, permitting the election of lady Fellows.

Prof. Turner followed with a biographical address, illustrated by portrait slides; he began with Queen Victoria, who had been their Royal Patron during two-thirds of their existence. He noted that former kings of Denmark and Siam had been honorary members, a distinction also awarded to Caroline Herschel, and several other famous lady astronomers, the latest being Miss Annie Cannon. The portraits included Sir W. and Sir J. Herschel, Francis Baily, Daniel Moore, Stephen Groombridge, Mr. Colebrook, Richard Taylor (first editor and printer of the Monthly Notices, and founder of the firm of Taylor and Francis).

The afternoon meeting was opened by the reading of the minutes of the preparatory meeting held at Freemason's Tavern, Gt. Queen St., Lincoln's Inn Fields, on January 8, 1820, at which Mr. Daniel Moore was chairman, the fourteen persons present all signing the declaration that they would help to forward the formation of the proposed Society.

Six of the Associates present were then invited to speak on their recent work. Dr. Seares spoke on the systematic differences of colours of giant and dwarf stars of the same type, the dwarfs being redder; he also discussed absolute magnitude as a function of galactic latitude. Prof. Strömgren spoke on solutions of the three-body problem by mechanical quadratures. Prof. H. Shapley spoke on his recent work of finding absolute magnitudes from objective prism spectra; also on the local cluster round the sun, stated to be 2000 light-years in diameter, and on the recent discovery of faint Cepheid variables in the Magellanic Cloud.

Dr. Hertzsprung spoke on the Cepheid variable RR Lyræ, showing that it has several superposed periodicities.

Dr. Aitken dealt with double stars, stating that his special aim was to form an exhaustive catalogue of all doubles down to the ninth magnitude within certain limits of distance. He stated that 15 per cent. of his discoveries already show orbital motion.

Dr. St. John spoke on the absence of the lines of oxygen and water vapour from the spectrum of Venus, stating that one metre thickness of each would have sufficed to give a register. He mentioned that the rotation of Venus is probably at least 15 days. The Einstein shift in the solar spectrum is still engaging attention. If present it is evidently partially masked by some other cause; the shift towards the red that is found is not proportional to wave-length.

The Society dined at the Criterion Restaurant in the evening. Lord Balfour was the guest of honour, and proposed the toast of the Society in felicitous terms, the president making a suitable reply.

On Wednesday the Fellows and Associates were the guests of the British Astronomical Association.

On Saturday, June 3, the Society was entertained by the Astronomer Royal at Greenwich on the occasion of the annual Visitation of the Observatory.

A. C. D. CROMMELIN.

University and Educational Intelligence.

LEEDS.—An open fellowship of 200*l*. per annum, established by the Institution of Gas Engineers, is offered for the prosecution of post-graduate research in gas chemistry. Applications will be received by the Registrar of Leeds University until June 19.

LIVERPOOL.—Honorary degrees were conferred at a special Congregation of the University held on May 19. The Bishop (the Right Reverend Francis James Chavasse), Mr. Justice Pickford (Baron Sterndale), and Sir Henry Alexander Miers, vice-chancellor of the University of Manchester, received the degree of doctor of laws; Dr. L. P. Jacks, Principal of Manchester College, Oxford, and Editor of the *Hibbert Journal*, that of doctor of letters, and Sir Charles Sherrington, Waynflete professor of physiology in the University of Oxford and president of the Royal Society, that of doctor of laws. For eighteen years Sir Charles Sherrington was the George Holt professor of physiology at Liverpool, and his services to the University College and University during that period are now remembered with deep affection and gratitude. The degree of doctor of engineering was conferred on Sir John A. F. Aspinall. Sir John Aspinall was for years chairman of the faculty of engineering at the University, and the present highly developed condition of the series of departments that now constitute the faculty is very largely due to the powerful influence that he exerted on its behalf. His professional career has seen the development of some highly important methods of modern railway transport.

LONDON.—The following Doctorates have been conferred:—*D.Sc. in Chemistry:* Mr. G. A. R. Kon, an internal student of the Imperial College—Royal College of Science—for a thesis entitled "The Influence of Space Conditions on the Formation of Strained Rings; The Formation and Stability of *spiro*-compounds." *D.Sc. in Cytology:* Mr. J. B. Gatenby, an internal student of University College, for a thesis entitled "The Cytoplasmic Inclusions of the Germ-cells: Part X.—The Gametogenesis of Saccocirrus." *D.Sc. in Physics:* Mr. L. C. Martin, an internal student of the Imperial College—Royal College of Science, for a thesis entitled "A Physical Study of Spherical Aberration." *D.Sc. in Physiology:* Miss Gladys A. Hartwell, an internal student of King's College for Women (Household and Social Science Department) and Bedford College, for a thesis entitled "Mammary Secretion." *D.Sc. in Botany:* Mr. W. J. Hodgetts, an external student, for a thesis entitled "A Study of some of the Factors controlling the Periodicity of Freshwater Algæ in Nature," and other papers.

Applications are invited for a Sharpey physiological scholarship at University College. The scholarship is of the value of 200*l*. Applications, with a full statement of the candidates' academic training and a list of their publications, if any, should reach the secretary of the college, Gower Street, W.C.1, not later than June 15.

A DRAPERS' COMPANY'S research scholarship in dyeing and a research scholarship in colour chemistry, tenable for the session 1922–23 at the Huddersfield Technical College, are offered. The value of the first-named scholarship is 100*l*. and remission of fees, and that of the last named not more than 100*l*. and remission of fees. All particulars and forms of application may be had from the secretary of the college.

Calendar of Industrial Pioneers.

June 10, 1850. James Smith died.—Educated at Glasgow University, Smith was placed in charge of his uncle's cotton-works at Deanston, Perthshire, where he introduced many improvements in manufacture and agriculture. He invented a reaping machine, improved the self-acting mule, built bridges and waterwheels, in 1813 lighted his factory by gas and introduced the sub-soil plough and the deep draining of soils.

June 11, 1843. Alexander Forsyth died.—The inventor of the percussion lock, Forsyth was born in 1769, graduated at King's College, Aberdeen, and from 1791 till his death was minister of his native place of Belhelvie. Devoting his spare time to chemistry and mechanics, in 1805 he brought out the percussion lock, which, though experimented with in the Tower of London, was not taken up by the Government. Forsyth refused an offer of 20,000*l.* from Napoleon for the secret.

June 13, 1847. David Mushet died.—A pioneer among modern metallurgists, Mushet began experimenting in the manufacture of iron and steel in 1793 while employed at the Clyde Iron Works. Dismissed through jealousy, he erected the Calder Iron Works, and while so engaged, in 1800 patented a process of making steel direct from iron in bars, and in 1801 made the discovery of the value of the black-band ironstone, which previously had been regarded as worthless.

June 14, 1768. James Short died.—In his day without a rival as a constructor of reflecting telescopes, Short was the first to give specula a true parabolic form. Born and educated at Edinburgh, where he learned mathematics from Maclaurin, he was summoned to London to give mathematical lessons to one of the royal family. He afterwards set up as an instrument maker in London.

June 14, 1874. Sir Charles Fox died.—Articled first to a doctor, Fox abandoned medicine for engineering, worked for Ericsson and Robert Stephenson, and became a partner in the firm of Fox, Henderson and Co., the first firm systematically to manufacture railway plant. Fox designed the buildings for the Great Exhibition of 1851, made the first narrow-gauge line in India, built the Berlin waterworks, and was connected with many railway enterprises.

June 15, 1905. James Mansergh died.—One of the greatest water-supply and sewerage engineers, Mansergh was responsible for works in some 60 or 70 towns at home and abroad. Among his most notable works were the Elan and Claerwen reservoirs in Wales, constructed for the Birmingham Corporation and opened by King Edward VII., July 21, 1904. In 1900 he served as President of the Institution of Civil Engineers.

June 15, 1915. Sir Nathaniel Barnaby died.—Barnaby came of a family of shipwrights, and was born at Chatham in 1829, the year the first British steam war-vessel was built. He was trained in the Royal Dockyard, and in 1870 succeeded Reed as Chief Constructor of the Navy, a post he held till 1885, when he was succeeded by White. To him were due many advances in the design and construction of warships; he introduced the use of steel, and during his regime sixty-six sea-going fighting ships of more than 2000 tons were built. The torpedo and torpedo boat came into use during his period of office, but he opposed the idea prevalent then, and periodically urged that the torpedo rendered the battleship obsolete.

E. C. S.

Societies and Academies.

London.

Royal Society, May 25.—Sir Charles Sherrington, president, in the chair.—C. H. **Lees**: The thermal stresses in solid and in hollow circular cylinders concentrically heated. The method of calculation is similar to that used in dealing with spheres. Two cases of practical importance are worked out—that of a furnace with the temperature throughout the wall steady, and that of a pillar supporting the floor above a room in which a fire occurs. Curves are given for the thermal stresses produced.—B. F. J. **Schonland**: On the scattering of β-particles.—N. K. **Adam**: The properties and molecular structure of thin films. Pt. II. Condensed films. Pt. III. Expanded films. Saturated and unsaturated fatty acids of the long straight chain series, and their derivatives, including esters, substituted ureas, an alcohol, amide, and nitrite have been studied. Below a certain temperature determined by the conditions, the molecules appeared to be closely packed or "condensed." Above this temperature greater areas on the surface were occupied, such films being called "expanded films." Two general types of condensed film were found: one in which the hydrocarbon chains are close packed, while in the other probably only the polar groups touch. In the temperature interval (about 25° C.) between fully condensed and fully expanded states, pressure-area curves resemble isothermals of a vapour near critical temperature. Probably expanded films resemble vapours in two dimensions. Increase in length of hydrocarbon chains raises the temperature of expansion regularly. The lateral attraction which tends to keep the molecules close packed therefore depends on the length of these chains. Probably the greater attraction between longer chains diminishes the area of the expanded films. The area actually filled by molecules both of saturated and unsaturated acids is probably nearly the same in expanded and in condensed films; therefore it is unlikely that the unsaturated linkage in oleic acid approaches the water closely, as was previously thought.—E. **Wilson**: On the susceptibility of feebly magnetic bodies as affected by compression. Rock specimens were examined and the compressive stress was necessarily limited to about 1200 kgm. per sq. cm. Some feebly magnetic alloys have also been tested. All the specimens are in the form of short bars about 4 cm. in length, with a cross-section either 1 cm. square or 1 cm. in diameter, and the compressive stress has been applied in the direction of the length of the bar. The susceptibility has been measured (*a*) in the direction of the stress and (*b*) at right-angles to it.—S. F. **Grace**: Free motion of a sphere in a rotating liquid parallel to the axis of rotation. The motion is a small disturbance from one of uniform rotation, like a rigid body due to a projection, parallel to the axis of rotation, of a sphere of density equal to that of the liquid and originally at rest relative to it. The path of the centre of the sphere is a straight line, and the motion is symmetrical about it. The sphere oscillates about a point with amplitudes which diminish rapidly, being less than 0·02 of the velocity of projection, after one revolution of the liquid. The velocity of the liquid in this line is oscillatory. The disturbance over the plane through the centre of the sphere perpendicular to the axis is oscillatory, and confined to the immediate neighbourhood of the sphere. The components of verticity contain terms proportional to the time, so that the assumptions of small motion are ultimately violated.

Society of Glass Technology, May 17.—Prof. W. E. S. Turner, president, in the chair.—J. **Currie**: Columnar structure in sandstone blocks. A glass tank furnace sprang a leak in the bottom and the metal drained through rapidly. A full heat of 1300° C. was maintained to facilitate the removal of the metal, but finally part of the crown of the furnace collapsed and the gas was cut off. After the tank was dismantled it was observed that the sandstones readily disintegrated into long prismatic columns, many of which were straight, but most of them showing a decided curvature. They were roughly pentagonal in section, and varied in thickness from 0·5-1·5 inches; some were trigonal, others tetragonal in form. The columns were intersected at more or less regular intervals by cross joints, so that the sandstone tended to break up into short columns five or six inches long, some of which were regularly prismatic, others tapering off to a point. The effect is probably due to the rapid expansion caused by the sudden increase of temperature from 800° C. to 1300° C. resulting from the break in the furnace, followed by sudden cooling when the gas was turned off. The formation probably started at the point of contact with the glass, and as has already been claimed for similar formations in Nature, columnar jointing is related to the planes of cooling.—F. W. **Adams**: Some practical notes on the manufacture of white glass in a tank furnace. It is necessary to have complete analyses of all batch materials used, especially the selenium decoloriser. The total iron content in the finished glass must be kept constant, and careful weighing and efficient mixing of the batch ingredients is essential. Melting temperatures should be kept constant by the use of pyrometers. Lehr temperatures should be correct for a given type of glass and kept constant. Two pyrometer stations in the lehr are advisable, and articles differing greatly in weight should not be put together in the same lehr. Selenium offers many advantages over other decolorising media, and will undoubtedly be as generally used in this country for making colourless glass as in the United States when the conditions for its application are more fully understood by manufacturers.

Royal Meteorological Society, May 17.—Dr. C. Chree, president, in the chair.—A. E. M. **Geddes**: Weather and the crop-yield in the north-east counties of Scotland. The methods of correlation have been applied to find the relation between the yield of the crops in the three north-east counties of Scotland and the "weather," including in this term temperature and rainfall. There is not sufficient uniformity in all the conditions over the area from Nairn to Fife to permit of useful deductions being drawn. The final investigation was confined to the counties of Aberdeen, Banff, and Kincardine for the period 1885 to 1919. The conclusions are as follows: cereals do better in a comparatively warm summer with rainfall somewhat in excess; root crops show less connection with the weather than cereals, but are better with rainfall below the normal; hay is influenced almost as much by the weather of the year previous as by that of the actual year of harvest. Comparing the latest values for eastern England for the same period, it appears that the most important sections of the year, so far as weather is concerned, vary from district to district. It is important not to make the district too wide in such investigations.—H. P. **Waran**: A new form of direct-reading barometer. The instrument is a modified syphon barometer that compensates automatically for the change of level. This is accomplished by reading axially through the inclined upper reservoir, the reflection on the mercury surface of the divisions of a short length of vertically suspended scale, which has once been set to read the actual pressure, on the cross-wire.

PARIS.

Academy of Sciences, May 15.—M. Albin Haller in the chair.—L. **Maquenne** and R. **Cerighelli**: The influence of lime on the yield of seeds during the germinative period. Traces of lime in the culture fluid (10 parts of calcium sulphate per million) favour the growth of the organs, and this is shown not only by increased length, as compared with control seeds grown in distilled water, but also by increase in weight.—Georges **Charpy** and Louis **Grenet**: Study of the penetration of tempering in steel. A method is described permitting the study of the variation in hardness (Brinell) along a bar, after tempering at different temperatures, with or without reheating, and not necessitating test pieces being cut out of the specimen.—Gustave **Guillaumin**: The equations of the limit of equilibrium of adherent bodies.—Jean **Chazy**: The movement of a planet in a resisting medium.—F. **Michaud**: The rigidity of jellies. A new method of measuring the rigidity of a jelly is described, based on the use of a horizontal tube filled with the jelly and carrying some solid particles in suspension, the movement of which, when the ends of the rod of jelly are submitted to different pressures, can be measured in a microscope. The apparatus has been applied to the measurement of the rigidity of 15 solutions of gelose of concentrations varying from 0·4 to 6 per 1000. The experimental figures can be expressed by the empirical formula $\mu = 6{\cdot}32\ (c - 0{\cdot}39)^{3{\cdot}3}$, where μ is the modulus of rigidity in C.G.S. units, and c is the number of grams of gelose per 1000 grams of the mixture.—Henri **Abraham** and René **Planiol**: A new method of emission doubling the capacity of wireless telegraphy stations.—A. **Grebel**: A comburimeter and a controller for gas, Grebel-Velter system. In the "comburimètre," the coal gas is burnt in air, the ratio of gas to air being capable of variation and measurement. A mirror surface of fused lead serves as the indicator for oxygen in excess, and the exact quantity of air required for the complete combustion of a given volume of gas is thus continuously indicated.—Mme. **Ramart** and M. G. **Albesco**: Study of the two $\alpha\alpha$. $\beta\beta$-substituted propiophenones and their reaction with sodium amide.—Marcel **Delépine**: The auto-oxidation of organic sulphur compounds. A detailed account of some phenomena observed when air and certain sulphur compounds (such as $SC(OCH_3)(S . CH_3)$; $CH_3 . CS . (OCH_3)$) interact. The observations cannot be fully explained.—Henri **Piéron**: The law of the velocity of establishment of the fundamental chromatic processes as a function of the intensity of the luminous stimulation.—Alphonse **Labbé**: The activation of the spermatozoid in heterogeneous fecundations.—Armand **Dehorne**: The formation of myolytic spindles and their phagocytosis in the cœlom of *Lipobranchus intermedius*. These organisms are extracted from old oyster shells by placing the latter in a crystallising basin filled with sea-water. The Lipobranchus can be seen swimming or attached to the sides of the basin. They are fixed living, and on microscopical analysis show marked phenomena of histolysis. It is remarkable that it is the muscles which show peculiar sensibility to this degeneration. The changes in the muscle fibres are described in detail.—C. **Gessard**: Varieties of pyocyanoid bacilli. The term "pyocyanoid" is applied to degenerate pyocyanic bacilli, which although retaining most of

their original properties have lost the essential characteristic of making pyocyanine. One variety gives no trace of the blue colouring matter in peptone water or peptone gelose, but the pyocyanine reappears if a small quantity of glycerol be added to the peptone gelose. In cultures with increasing quantities of glycerol, the power of producing the blue pigment is lost.—Albert **Berthelot** and Mme. **St. Danysz-Michel**: The presence of acetone-producing micro-organisms in the intestinal flora of diabetics. Cultures from fæcal matter of 32 subjects, not diabetic, but suffering from various diseases, showed that no organism was present capable of producing acetone from starch. From similar cultures with fæces from diabetic patients, acetone-producing organisms were found in 17 cases out of 22. The view that diabetes is a disease of microbial origin is not in agreement with the present state of knowledge of this disease, but it is not altogether impossible that certain cases of diabetes may be caused, directly or indirectly, by the presence of certain micro-organisms in the intestine.—M. **Breton** and V. **Grysez**: The reactions of defence and immunity provoked by the intradermic injection of micro-organisms, either living or killed by heat. The skin of the rabbit possesses exceptional properties of defence against organisms inoculated there: immunity has been produced by a single injection.

Official Publications Received.

Annals of the Astronomical Observatory of Harvard College. Vol 86, Part 1: Observations and Investigations made at the Blue Hil Meteorological Observatory in the Year 1921 under the direction of Prof. A. McAdie. Pp. 61. (Cambridge, Mass.)

Egyptian Government. Almanac for the Year 1922. Pp. viii+242. (Cairo: Government Publications Office.) P.T. 10.

Dominion of New Zealand: Board of Science and Art. Bulletin No. 2: History of the Portobello Marine Fish-Hatchery and Biological Station. By the Hon. Geo. M. Thomson and the late T. Anderton. Pp. 131. (Wellington, N.Z.)

Annual Report of the Council of the Yorkshire Philosophical Society for the Year 1921, presented to the Annual Meeting, February 13th, 1922. Pp. 51. (York.)

The Royal Society for the Protection of Birds. Thirty-first Annual Report, January 1st to December 31st, 1921, with Proceedings of Annual Meeting, 1922. Pp. 76. (London: 23 Queen Anne's Gate, S.W.1.)

Diary of Societies.

FRIDAY, JUNE 9.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) AND BRITISH ASSOCIATION FOR THE ADVANCEMENT OF RADIOLOGY AND PHYSIOTHERAPY (at 1 Wimpole Street), at 10.30 A.M. and 2.30.—Congress of Radiology and Physiotherapy.

PHYSICAL SOCIETY OF LONDON, at 3.30.—Visit to the National Physical Laboratory, Teddington.

ROYAL SOCIETY OF ARTS (Dominions and Colonies Section), at 4.30.—Major Sir Humphrey Leggett: Tanganyika Territory (formerly German East Africa).

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society).

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—Dr. A. E. Trueman: The Liassic Rocks of Glamorgan.—C. C. Fagg: The Recession of the Chalk Escarpment and the Development of Valleys in the Chalk between the Mole and the Darenth.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Annual General Meeting.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—J. Barcroft: Physiological Effects at High Altitudes in Peru.

SATURDAY, JUNE 10.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section) AND THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF RADIOLOGY AND PHYSIOTHERAPY (at 1 Wimpole Street), at 10 A.M. and 2.30.—Congress of Radiology and Physiotherapy.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Hugh Allen: Early Keyboard Music (3).

MONDAY, JUNE 12.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Miss A. M. Hodgkin: The Witness of Archæology to the Bible.

INSTITUTE OF ACTUARIES, at 5.—Annual General Meeting.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

SOCIETY OF ENGINEERS (at Geological Society of London), at 5.30.—Dr. H. Chatley; A. S. E. Ackermann: The Physical Properties of Clay.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Business Meeting.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—T. Greenwood: Geometry and Reality.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall, 135 New Bond Street), at 8.30.

ROYAL SOCIETY OF MEDICINE (Tropical Diseases and Parasitology Section), at 8.30.—Sir Leonard Rogers: Leprosy: its Etiology and Epidemiology.—D. Pinnock: Quinine Necrosis of Muscles.—Dr. J. Bamforth: Cortical Necrosis of the Kidney in a Fatal Case of Malaria.

TUESDAY, JUNE 13.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. G. Holmes: The Symptoms of Cerebellar Disease and their Interpretation (Croonian Lectures) (2).

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: The Council's Scheme to establish an Aquarium in the Society's Gardens.—Miss Joan B. Proctor: A Study of the Tortoise *Testudo loveridgii*, Blgr., and the Morphogeny of the Chelonian Carapace.—J. T. Carter: A Microscopical Examination of the Teeth of the Primates.—H. G. Jackson: A Revision of the Isopod Genus Ligia (Fabricus).—W. R. B. Oliver: A Review of the Cetacea of the New Zealand Seas.—Prof. Wood Jones: The Dental Characters of certain Australian Rats.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—F. T. Usher: Matt Surface Plates.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—E. K. Maxwell: Some Tubular Rotifers.—F. H. Davidson: Demonstration of Microscope and Super-Microscope.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Prof. G. Elliot Smith and Prof. J. I. Hunter: A Reconstruction of the Piltdown Skull.

RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.—Dr. F. L. Hopwood and Dr. E. A. Owen: German Apparatus for the Production and Measurement of X-rays for Deep Therapy.—Prof. S. Russ and L. H. Clark: A Balance Method of Measuring X-rays for Therapeutic Purposes.—Dr. F. L. Hopwood: The Ondoscope.—Dr. E. A. Owen: The Sphere Gap Voltmeter.

SOCIOLOGICAL SOCIETY (at Royal Society), at 8.15.—G. K. Chesterton: The Return of the Guilds.

WEDNESDAY, JUNE 14.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. P. G. H. Boswell: The Petrography of the Cretaceous and Tertiary Outliers of the West of England.—Prof. W. N. Benson and Dr. S. Smith: Some Rugose Corals from the Burindi Series (Lower Carboniferous) of New South Wales.

ROYAL MICROSCOPICAL SOCIETY, at 8.—J. Strachan: The Microscope in Paper Making.—A. Chaston Chapman: The Use of the Microscope in the Brewing Industry.

THURSDAY, JUNE 15.

ROYAL SOCIETY, at 4.30.—*Probable Papers.*—Dr. H. M. Evans: The Defensive Spines of Fishes, Living and Fossil, and the Glandular Construction in connection therewith, and Observations on the Nature of Fish Venoms.—D. W. Cutler, L. M. Crump, and H. Sandon: A Quantitative Investigation of the Bacterial and Protozoan Population of the Soil: with an Account of the Protozoan Fauna.—D. W. Devanesen: The Development of the Calcareous Parts of the Lantern of Aristotle in *Echinus miliaris*.—Dr. A. Lipschütz, C. Wagner, R. Tamm, and F. Bormann: Further Experimental Investigations on the Hypertrophy of the Sexual Glands.

LINNEAN SOCIETY OF LONDON, at 5.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. G. Holmes: The Symptoms of Cerebellar Disease and their Interpretation (Croonian Lectures) (3).

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Lieut.-Col. A. Ogilvie: Some Aspects of Aeronautical Research (Wilbur Wright Lecture).

NATIONAL UNION OF SCIENTIFIC WORKERS (in Botanical Theatre, University College), at 5.30.—F. W. Sanderson: The Duty and Service of Science in the New Era.

CHEMICAL SOCIETY, at 8.—C. K. Ingold and E. A. Perren: Ring-chain Tautomerism. Part III. The Occurrence of Tautomerism of the Three-carbon (Glutaconic) Type between a Homocyclic Compound and its Unsaturated Open-chain Isomeride.

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, JUNE 9.

UNIVERSITY COLLEGE, at 5.30.—Prof. E. Husserl: Phänomenologische Methode und Phänomenologische Philosophie (3). (In German.)

MONDAY, JUNE 12.

ROYAL SOCIETY OF MEDICINE, at 5.—Dr. M. Jansen: Injurious Agents and Growth. (In English.)

UNIVERSITY COLLEGE, at 5.30.—Prof. E. Husserl: Phänomenologische Methode und Phänomenologische Philosophie (4). (In German.)

TUESDAY, JUNE 13.

FELLOWSHIP OF MEDICINE (at 1 Wimpole Street), at 5.—Sir William Hale White: The Clinical Symptoms of Coli Infection of the Urine.

KING'S COLLEGE, at 5.30.—C. E. M. Joad: Vitalism Restated (2). Dualism and the Life Force.

THURSDAY, JUNE 15.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 5.—Prof. C. H. Reilly: Some London Streets and their Recent Buildings.

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 5.—Sir Berkeley G. A. Moynihan: Diverticula of the Alimentary Tract.

SATURDAY, JUNE 17, 1922.

The Genesis of the World.

"WHENCE sprang this world, and whether framed
By hand divine or no—"

are questions that have fascinated and perplexed the greatest thinkers of every age, or at least since man reached such a level of intellectual evolution that he could speculate about them. If we may reason from our knowledge of the mentality of the lowest grades of humanity as we know them to-day, it is reasonably certain that man must have existed on the earth for æons before he attained to a degree of mental development that would enable him to give the slightest consideration to such matters. Anthropologists tell us that even in this twentieth century there are races of men, situated in remote and widely separated regions of the world, who have never framed, and, so far as can be discovered, have never attempted to frame, any conception or surmise concerning its origin. And yet these races are as far removed in development from the prehistoric man as the prehistoric man was from the ape.

It is nevertheless true that thousands of years before the beginning of our era there were some whose mental powers enabled them to ponder upon the problem, and to attempt to form the beginnings of a theory of creation which should in some measure satisfy their curiosity and reasoning faculty. But these people existed comparatively late in the history of mankind, and still later in the history of the world. We are apt to think that the legends of Brahma, the spirit who created by his will and the mere exercise of thought the primeval water, the primordial element out of which the world was fashioned, date from the remotest periods of antiquity. This is not so, as we now reckon the age of the world, or the time that man has existed upon it.

It is far from our present purpose to attempt to trace, however slightly, the broad outlines of the growth of knowledge and speculation concerning the genesis of the world—from the myths of primitive races down to our times, when the great enigma is being attacked by modern methods of research and in the light of contemporary science. The subject is too vast to be handled within the narrow confines of an article such as this. But it may be worth noting how characteristic is the difference between the modern methods and the old. The earliest cosmogonies were based upon conceptions which were really incompatible with the experiences of those who framed them. These conceptions must have been repugnant to the intelligence of all who were alive to the teachings of natural phenomena, or refused to blind their reason at the behests of the priests by whom the myths were devised. In one respect the speculations, or at least some of them, may be said to be so far scientific in that they contain the

germ of the theory of evolution. But they all presupposed the action or intervention of supernatural forces, and as such had no real scientific basis. Purely metaphysical speculation leads nowhere, and the unsubstantial subtleties of dialecticians leave us cold. We seek to elucidate what has been for countless ages an inscrutable problem in the light of the lessons of physical science. We reason from the facts of astronomy, geology, physics, chemistry, and biology as we know and understand them, and as each new development arises we apply its teaching to the solution of the mystery. It has already been pointed out that the application of the mechanical theory of heat, spectrum analysis, thermal radiation, radiation pressure, and radio-activity to cosmogonic phenomena has done more to elucidate these problems than all the speculative theories and systems of former ages put together.

The lecture[1] which Prof. Nernst reprints in the little brochure before us is, we believe, the latest attempt to focus the outcome of modern research upon this question of the origin and mode of formation of the world. He applies to it the knowledge with which his study and training as a worker and expositor of chemical physics has equipped him. Furthermore, he has sought the aid of students in fields of inquiry other than his own when these have any direct relation to his subject. The lecture was originally delivered in Berlin as one of a series of popular discourses arranged by the Prussian Academy of Sciences about a year ago, and has been repeated in parts of mid-Europe, notably in Vienna and in Prague. As published it has been considerably enlarged. It is prefaced by a short introductory statement defining the problem and explaining its limitations, and the methods by which it may be attacked. It is furnished with a long appendix, practically as extensive as the lecture itself, in which details are developed which would be out of place in a purely popular exposition. As may be anticipated, the whole is instructive and highly suggestive, and we have read it with interest and pleasure. Nevertheless we rise from its perusal with a humbling sense of the inadequacy of our present means to grapple with so stupendous a problem. More than ten years ago the same theme was handled by Prof. Svante Arrhenius in his "Werden der Welten" and afterwards in "The Life of the Universe," and it may be doubted whether in reality Prof. Nernst has succeeded in carrying the matter any further. How partial and inadequate is the basis on which even the latest cosmogony rests was well brought out in the discussion last year at the Edinburgh meeting of the British Association on the age of the earth. The work of one epoch does little more than upset that of its predecessor. Premises in regard to the earth's heat are vitiated by the discovery of radio-active materials. We are still in ignorance as to the true source of solar energy. Secular contraction apparently is not enough to account for it. We have absolutely no definite knowledge on so fundamental a matter. The more we learn the greater seems our ignorance. We can but go on groping for the light, testing our surmises as best we may in the feeble glimmer that our present knowledge sheds.

Negligible as is the scientific merit of the old cosmogonies, they had at least the charms of imagery and fancy—charms at which the cold, unsympathetic eye of a passionless science looks askance. Even the imagination of a Tyndall would find it difficult to invest our modern cosmogony with the vestiges of such attributes.

[1] "Das Weltgebäude im Lichte der Neueren Forschung." Von Prof. Dr. W. Nernst. Pp. iv+63. (Berlin: Julius Springer, 1921.) In Germany, 12 marks; in Great Britain, 48 marks.

Textile Research Fellowships.

THE British Research Association for the Woollen and Worsted Industries represents the culmination of a movement which was started at the University of Leeds during the early days of the war. Two objectives were then in view, research specially applied to the elucidation of problems presented by the textile industries, and a deeper and more extensive education with the object of promoting the introduction of the sciences and scientific method into industry whenever and wherever possible. It was perhaps natural that the first of these objectives should dominate when, in what it conceived to be the larger interest of the community, the University handed over its missionary work to the newly constituted Research Association, which included representatives from the whole of the woollen and worsted industries of Great Britain and Ireland.

The experience of this association is now tending to emphasise the need for well-trained, sympathetic men actually placed in the works if the achievements in research—which already are by no means inconsiderable—are to be used at all: still more is this necessary if anything like full value is to be drawn from research results.

It is therefore not surprising that the research association should consider it not only expedient but also absolutely necessary that well-trained University and other students should be encouraged to resist the more direct call of industry and to prepare themselves for the difficult but very necessary work of introducing more science into industry. Whether this appeal will achieve the desired result depends not only upon the fellows and scholars which the association is now selecting, but also upon the sympathetic consideration given to their work and its possibilities by the controllers of industry. In addition to ability, there must

be opportunity, and only the combers, spinners, and manufacturers can give this.

We have confidence that the necessary opportunity will be given to the well-trained man, and we therefore specially direct the attention of those eligible for the fellowships and scholarships offered by the British Research Association for the Woollen and Worsted Industries. In each case awards are tenable in the first place for one year, and maintenance grants are offered, the maximum value of the fellowships being fixed at 200*l.* per annum. Applications for fellowships, which should reach the secretary of the association at Torridon, Headingley, Leeds, before June 30, should contain full particulars of the candidates' training and an outline of the research which it is proposed to undertake. It should be realised, however, that if success is to be achieved a type of "researcher" different from any yet produced is necessary. The man of science has as yet made little or no direct impression upon the woollen and worsted industries; all the advances made —and these have been more considerable than most people realise at the present moment—have been at the hands of the technologist. Indeed, it is still a moot point as to whether the technologist should be encouraged to obtain a training in pure science, or whether the man of science should become a technologist. Possibly both these lines of action are promising, but from the scientific point of view it is very desirable that prospective candidates should have a sound knowledge of the industry, for with this knowledge and deeper insight will undoubtedly come a profound respect for an industry which has already achieved so much, and further an earnest desire to help towards increasing its usefulness in the service of humanity.

Possibly the textile industries offer most promising fields of research in the direction of physical chemistry; but applied mathematics, chemistry, zoology, and other of the sciences have also claims which will certainly not be ignored.

A Manual of Tides.

Tides and Tidal Streams: A Manual compiled for the Use of Seamen. By Comdr. H. D. Warburg, R.N. Pp. vii+95. (Cambridge: At the University Press, 1922.) 8*s.* 6*d.* net.

THE author of this manual is convinced, and not without cause, that the non-harmonic methods of giving and using tidal information at ports not served by complete predictions are obsolete and not trustworthy. These methods assume the simple phenomenon of semi-diurnal tides only and came into prominence because the original workers on tides were most familiar with the tides in European waters. But in most parts of the world the diurnal tides cannot be neglected, even if they are not of greater importance than the semi-diurnal tides, and at present navigators are not provided with information suitable for the calculation of tidal heights in such places. Commander Warburg suggests that the tides should be represented universally by a few harmonic constituents, and that navigators should be taught suitable methods for getting approximate values of the height of tide at any time by the use of harmonic methods.

The author gives an explanation of the generation of tides and tidal currents as an introduction to the harmonic methods proposed, and he also explains various tidal phenomena such as the double high-waters experienced on the south coast of England, but these explanations cannot always be commended from the scientific point of view. The phenomenon of double high-waters, incorrectly explained in the manual, has often been explained correctly from Airy onwards (*e.g.* Sir W. Thomson, NATURE, Dec. 19, 1878), but the wrong explanation is curiously persistent. It is alleged that the cause is in the reflection of the tide wave from the north coast of France and that this "reflected wave" arrives on the south coast of England some six hours later than the "primary wave"; we thus get, it is said, two waves with their maxima some six hours apart and therefore two high-waters within six hours of one another. But obviously, or at least from simple trigonometry, two semi-diurnal oscillations, whatever be their relative phases, can only combine to give a semi-diurnal oscillation; that is, the part played by reflection is to make the resultant phase of the actual oscillation at a given place different from what it would have been if no reflection had taken place. The true cause is the presence of quarter-diurnal oscillations in the primary wave. These are due chiefly to shallow water, and with a free unreflected progressive wave the phases of the semi-diurnal and quarter-diurnal oscillations are such that double high-waters cannot occur; but if reflection takes place then it is possible to disturb this phase relationship so that the minimum of the resultant quarter-diurnal tide occurs about the time of maximum of the semi-diurnal tide; we may then get a "double-headed tide," or a very long "stand." The importance of the shallow-water constituent is, however, not limited to double high-water phenomena, which are only extreme cases.

A brief explanation of the mechanical harmonic method of calculating predictions is given, but the diagram of a tide-predicting machine, however, illustrates motions which are not strictly harmonic. The

author might justly complain that a similar diagram has been allowed to pass for several years without comment in the Admiralty Tide Tables!

For the calculation of approximate predictions Van der Stok's scheme of calculation is explained and used in the book, and the calculations are facilitated by appropriate tables. Some little confusion is caused, however, by using the same symbol (k) for the phase-lag (in degrees) and time-lag (in hours) when the tidal constituent is referred to a fictitious satellite; it is customary to use κ for the phase-lag. It is doubtful whether it was wise to depart from the usual rule of stating the astronomical argument; it is customary to make the speeds positive and the arguments therefore increase with time. Except to those using the harmonic method for the first time there is a liability of confusion between theory and practice, a positive speed and a decreasing argument being difficult to reconcile. If, however, the instructions are carefully followed the required predictions can be readily obtained, whether there is much or little diurnal tide.

It ought to be added that a criterion given for the relation between semi-diurnal and diurnal tides so that one maximum per day only can occur, has a very limited application.

The manual gives authoritative explanations of the non-harmonic methods of collecting and using tidal information. In spite of the blemishes mentioned above, the book should serve a useful purpose in making seamen acquainted with the reasons why such methods are often futile. At the same time, it provides an alternative and more exact method, and in doing this Commander Warburg has initiated a movement which, we hope, will lead to much-needed reforms in the everyday applications of tidal science.

A. T. DOODSON.

Electrothermic Processes in Steel Manufacture.

The Electro-Metallurgy of Steel. By C. C. Gow. (A Treatise of Electro-Chemistry. Edited by Bertram Blount.) Pp. xvi+351. (London: Constable and Co., Ltd., 1921.) 27*s*. 6*d*.

WHAT are usually called electro-metallurgical processes of steel manufacture now constitute an applied science of considerable industrial importance. Strictly speaking, however, the processes are not electro-metallurgical since electrolysis is not an essential feature. Electrical energy is transformed into heat energy which is applied to the making and refining of steel of many types. The possibility of applying electrical energy in this way was first demonstrated by the late Sir William Siemens almost twenty years before its commercial possibilities were recognised by later investigators. Prior to the outbreak of the late war the electric furnace had only a very limited application in steel metallurgy. Since then it has had a rapid and vast development, due partly to the shortage of high-grade raw materials, partly to the enormous demand for alloy steels, and partly to the need for utilising in some way the vast accumulation of heavy steel turnings. These conditions presented an exceptional opportunity for the electric furnace, and it was only then that its economic advantages in certain branches of steel-making were actually demonstrated. According to Mr. D. F. Campbell, who has written a preface to Mr. Gow's book, the electric furnace is now absorbing millions of electrical horse-power for various purposes and has produced more than a million tons of steels of various types.

Mr. Gow is well fitted to write a book on electrothermic processes of steel manufacture, both on account of his scientific training and his wide experience of steel works practice. These qualifications have stood him in good stead in producing a book which should attract the attention both of students of metallurgy and practical steel-makers. Following an introductory chapter on the historical development of electric steel furnaces, the early chapters deal with the general principles and application of alternating currents. In writing these the author expresses his great indebtedness to Mr. R. P. Abel. Then come chapters on electrothermal methods of melting and refining cold charges and refining liquid steel, and these in their turn are followed by a chapter on ingot casting. Later chapters deal with characteristic principles and features of electric furnace design and modern types of furnaces, suitable refractory materials, and the properties and manufacture of carbon electrodes. Finally, there is an appendix detailing rapid methods of analysis of bath samples.

The melting of steel on a large scale in a strictly reducing atmosphere is possible only in the electric furnace. New phenomena are observed and striking results have been obtained. It is therefore correct to say that the electric furnace gives the steel-maker and refiner a new atmosphere in which to conduct his operations. Owing primarily to the much higher temperatures which can be reached, steels of inferior grade can be melted and their deleterious constituents to a great extent removed, because it is possible to introduce refining slags which can be fused and operated only at temperatures reached in the electric furnace. This type of furnace has now rendered available new alloys of special value, such as low carbon ferro-chromium, and high-grade ferro-silicon, which in their turn have

been economically transformed into products such as stainless steel, stainless iron, and transformer iron. The use of the last named has increased the efficiency of electric transformers to an extent which represents an annual saving of hundreds of thousands of tons of coal per annum.

At one time the induction furnace received considerably greater prominence than the arc furnace. As the author states, many furnace designers, believing that the principle of induction heating was superior, concentrated their efforts on the production of a furnace which could operate on any standard electric supply and at the same time meet all the requirements of the steel-maker. The position to-day, however, is that almost the entire output of electric steel is made from arc furnaces. The book is clearly printed and well illustrated and will certainly repay study by all those interested in the subject.

Physiology of the Growing Plant.

Encyclopédie scientifique: Bibliothèque de Physiologie et de Pathologie végétales: Nutrition de la plante. Par M. Molliard. I. Echanges d'eau et des substances minérales. Pp. xiv+395. II. Formation des substances terraires. Pp. vi+438. (Paris: Gaston Doin, 1921.) 14 francs each vol.

A SERIES dealing with the physiology of the growing plant in health and disease is being written by Prof. Molliard, Dean of the Faculty of Science of the University of Paris, and the two volumes under notice are the first to be issued. The scope of the series is wider than would usually be undertaken by a single writer, but the author considers that the advantages of uniform treatment will outweigh the disadvantages arising from the attempt to cover so extensive a field of science.

The volumes before us deal with the nutrition of the plant, the phenomena of absorption of nutrients from the soil, the building up of complex substances in the plant and their translocation from leaves to storage organs. The author has succeeded in bringing together a great amount of material that cannot usually be found in the same book, and this will prove a convenience to students. As an example, under the heading "Glucosides" there is not only the usual chemical account of these substances, but illustrations of cross-sections showing the distribution of typical glucosides in growing plants. In this and in other directions, the volumes give to the chemist much information that he does not possess although it may be well known to the botanist, and they give to the botanist a survey of chemical relationships which he might not find so easily elsewhere.

It could scarcely be expected that a book covering so much ground could include anything like all the recent work. The section on soils, for example, contains no reference to many of the investigations made during the last few years. The only grouping of fractions in mechanical analysis of which mention is made is that of Wollny, drawn up forty years ago, no reference being made to the important later developments made in the United States, Great Britain, Sweden, or elsewhere. Similarly also, it is assumed that soil possesses the sand-grain structure formerly attributed to it, although this view is now displaced by the later colloidal hypothesis. Fuller justice is done, however, to recent French work, and it is in the summaries of some of these interesting and suggestive investigations that English readers will find the chief interest of the book.

We should like to suggest that in future volumes there should be more references showing the sources from which the tables are taken. A considerable number of figures are given, but it is not easy to know the exact conditions under which they were obtained, and, as every one who has studied plant nutrition is aware, the phenomena are profoundly affected by alterations in the conditions under which the plant is growing. In particular the section dealing with the mineral constituents of plants would have been greatly improved by fuller references.

Life among the Sema Nagas.

The Sema Nagas. By J. H. Hutton. Published by the direction of the Assam Government. Pp. xviii+463. (London: Macmillan and Co., Ltd., 1921.) 40*s*. net.

MR. HUTTON has quickly added to his monograph on the Angami Nagas a second describing the allied tribe, the Sema. The latter occupy the watershed dividing Assam from Burma, the plateau and the valleys of three rivers, the most important, the Dayang, eventually flowing into the Brahmaputra and so into the Ganges, the other two mingling their waters with the Lania, and reaching the sea by way of the Ti-Ho, the Chindwin, and the Irawadi. The Sema Nagas are a mixed race, the result of emigration from at least three directions: from the north-west, whence came the Singpos, Kacharis, and Garos; from the south the Angamis; while a migration from south northwards on the part of the Thado Kukis and Lusheis has scarcely ceased even now.

Mr. Hutton's work is the result of eight years' acquaintance with the Sema Nagas, during which he learned to speak their language, which had not hitherto been reduced to writing, and gained the confidence of a

semi-savage people. He has thus had the opportunity of producing a fine, original work in ethnography, his memoirs being more elaborate than the other volumes of this excellent series which we owe to the enterprise and liberality of the Government of Assam.

Previous writers have found little that is favourable in the character of the Sema, and speak of their cruelty in war, their treachery and habit of lying. But Mr. Hutton, himself an Irishman, describes them as the Irishmen of the Naga race, generous, hospitable, and frequently improvident, impulsive and cheery, if easily depressed quickly regaining their spirits, readily moved to laughter and merriment under the most unpleasant conditions, while they still preserve a strong vein of fatalism. Their physical endurance in carrying heavy loads for long distances, in bearing cold and exposure, is remarkable, and in warfare and hunting, at any rate by Naga standards, they are plucky and daring. Their women, in appearance stumpy, plain or even ugly, are cheerful, faithful wives and dutiful daughters. Their art is limited to the decoration of their dress, weapons, and the Genna posts which mark the taboo limits of their villages.

As is usually the case with semi-savage tribes, the Sema live under a rigorous system of taboos, much more restrictive than those of the Hindu caste system. This type of taboo, known as Genna, is largely regulated by the agricultural seasons, and is enforced at sowing, harvest, and other farming operations. On such occasions work is suspended and special diet with numerous other trivial restrictions is enforced. They believe in a Creator, vaguely conceived, who interferes little in the affairs of men, in spirits of the sky and of the wild, spirits which cause delirium, spoil the crops and breed strife and quarrels, the spirits of the dead which fetch the living when they die. The basis of society is not the tribe or the clan, but the village, and they have evolved an elaborate system of social law. They manufacture for their own use excellent cotton cloth, not using fibres as the Angami do. Iron work is of recent introduction and follows methods borrowed from adjoining tribes. In spite of this advancement in social and industrial culture, head-hunting, success in which entitles the hero to wear gauntlets decorated with cowry shells and a collar of pigs' tushes, prevails, and the heads of women are specially valued, probably because they are secured with difficulty, women working only near the village in time of danger.

Mr. Hutton has described this strange type of society with wide knowledge and sympathy. His book is comprehensive, well arranged and supplied with maps and illustrations. Mr. H. Balfour, who writes a foreword, does full justice to it as an ethnographical study, and he informs us that Mr. Hutton has liberally presented to the Pitt Rivers Museum the greater part of his fine collections, an important gift to his old University.

More Books on Relativity.

A Criticism of Einstein and his Problem. By W. H. V. Reade. Pp. vi + 126. (Oxford: B. Blackwell, 1922.) 4*s.* 6*d.* net.

Relativity for All. By Herbert Dingle. Pp. viii + 72. (London: Methuen and Co., Ltd., 1922.) 2*s.* net.

Einstein and the Universe: A Popular Exposition of the Famous Theory. By Charles Nordmann. Translated by Joseph M'Cabe. Pp. 185. (London: T. Fisher Unwin, Ltd., 1922.) 10*s.* 6*d.* net.

Le Principe de Relativité et la Théorie de la Gravitation. Leçons professées en 1921 et 1922 à l'École polytechnique et au Muséum d'Histoire naturelle. Par Prof. J. Becquerel. Pp. ix + 342. (Paris: Gauthier-Villars et Cie, 1922.) 25 francs.

La Théorie einsteinienne de la Gravitation: Essai de vulgarisation de la théorie. Par Prof. Gustave Mie. Ouvrage traduit de l'allemand. Pp. xi + 119. (Paris: J. Hermann, 1922.) 4·50 francs.

L'Éther actuel et ses précurseurs (simple récit). Par E. M. Lémeray. Préface de L. Lecorme. Pp. ix + 141. (Paris: Gauthier-Villars et Cie, 1922.)

Raum und Zeit im Lichte der speziellen Relativitätstheorie. Versuch eines synthetischen Aufbaus der speziellen Relatitivätstheorie. Von Dr. C. Von Horvath. Pp. v + 58. (Berlin: Julius Springer, 1921.) England, 36 marks; Germany, 12 marks.

THE stream continues. Here are seven more books on relativity. It is difficult to know where to begin in commenting on such a collection. Mr. Reade's perhaps may be dismissed with a word; it ought not to have been written. Mr. Dingle's, on the other hand, is a serious little book by one who has caught the spirit of the matter. Within the limits of seventy small pages, without any mathematical symbols, he has done as well as can be expected in suggesting the various strains of thought that go to the making up of the theory. It is neither extravagant nor childish; it gives enough and not too much emphasis to illustrative analogies. The reader of this account may be assured that he is not being misled.

M. Nordmann's work, to which Viscount Haldane contributes a preface, is a much more ambitious production than that of Mr. Dingle and calls for more lengthy comment. To quote from the preface:

"The Latin capacity for eliminating abstractness from the description of facts is everywhere apparent. . . . This book could hardly have been written by an Englishman. The difficulty in his way would have

been one as much of spirit as of letter. It is the lucidity of the French author, in combination with his own gift of expression, that has made it possible for the translator to succeed so well in overcoming the obstacles to giving the exposition in our own tongue this book contains. The rendering seems to me, after reading the book both in French and in English, admirable."

The book is certainly readable. The language is not only clear, but also picturesque. "Einstein may be a treasure, but there is a fearsome troop of mathematical reptiles keeping inquisitive folk away from it. Let us drive them off with the whip of simple terminology, and approach the splendour of Einstein's theory." This is the author's intention, like that of many others ; how does he succeed ?

In the first two chapters we may admit a considerable success. Here due recognition is given to the valuable work done by Poincaré in preparing the minds of physicists for the theory by his insistence on the relativity of space. The reader is brought to the point of seeing the confusion wrought by the unexpected result of the Michelson-Morley experiment.

At the third chapter the author begins to feel the excitement of Einstein's new thoughts, and gives us a version of the explanation advanced in 1905 of the true significance of the Fitzgerald contraction-hypothesis. With the gesture of a conjurer he produces a "simple" version of Einstein's argument, remarking, however, that its elementary simplicity has not been attained without difficulty. Unfortunately the explanation advanced has nothing whatever to do with the argument of Einstein or the Fitzgerald hypothesis, but refers to the first order effect which would arise if the old theory were true. Later in the chapter the footnote giving as the best definition of the second, "the time which light takes to cover 186,000 miles in empty space, far from any strong gravitational field" suggests again quite a wrong view to the unwary and inexperienced reader. In spite, however, of these inaccuracies the writer does convey something of the impression of the insufficiency of the old absolute time and space ideas, and describes the situation thus : "We have before our eyes merely a battlefield strewn with corpses and ruins." "Time and space lie, torn and crumbled, among the rubbish of ancient theories."

Now comes the task of describing in "simple terminology" the work of reconstruction. The reader must judge whether the following is simpler than a brief algebraic equation : "The distance in time and the distance in space are numerically to each other as the hypotenuse and another side of a rectangular triangle are to the third side, which remains invariable. Taking this third side for base, the other two will describe above it, a triangle more or less elevated according as the velocity of the observer is more or less reduced. This fixed base is a quantity independent of the velocity. It is this which Einstein has called the '*Interval*' of events." A few lines later we read that this interval is the "sole perceptible part of the real. Apart from it there is nothing we can know." With this the writer passes on to the next chapter. Here the mechanics arising out of the restricted principle of relativity is described clearly and without rhetoric.

We have now to see how the author deals with the generalised relativity and its consequences. If the reader has digested the idea of interval so rawly presented to him in the early chapter, and has not the quickness to perceive that this has not been extended to the generalised theory, he may get a general impression from the next two chapters which is of the right type, but which again is far from accurate in detail. It appears from the account given that the only new feature in this stage is the introduction of gravitation. Not a word is said about the application of the general doctrine that all physical laws must have a form which is independent of the arbitrary choice of variables in the four-dimensional continuum. The mathematical reptiles are certainly driven off, and the treasure is not only left unguarded but it disappears. What is left is not the genuine article. Here again there are inaccurate statements, *e.g.* "the universe is not Euclidean because in it light does not travel in a straight line."

It is no pleasure to write thus critically of a valiant attempt to bring this theory into a form suitable for the layman. It is a supremely difficult task that is being attempted by so many writers. M. Nordmann is well equipped in many ways for it. But he has fallen into the very common error of supposing that the essential truth can be given while omitting the demand for concentrated thinking on vital details. The world suffers far too much from loose thinking already. Vague generalisations, misleading analogies, superficial manifestations are made to do duty for precise statements, logical reasoning, and fundamental principles. It is not necessarily true that mathematical skill is the only way of approach to an understanding of Einstein's fundamental ideas. But it is certain that if such an understanding is to be reached it can only be by going down to a patient analysis of our own preconceived notions until we find them insufficient. Einstein's success has come from a deep-rooted conviction that those thinkers were right who would not admit that a point in empty space could be labelled "stationary" or "moving uniformly in a straight line." He followed the logic of his conviction

and achieved fame. It was accuracy and honesty of thought which carried him through.

Prof. Becquerel gives us a text-book of the whole matter for those who are prepared to go into the complete mathematical presentation. There is nothing original; it is a plain and unvarnished account of the theory as it stands, including the generalisations of Eddington and Weyl. We may note that the author adopts the general conclusion that the gravitational field is the manifestation of the non-Euclidean character of the structure of the Universe, and that mechanics and physics are reduced to geometry. Is it not time that this statement should be examined more carefully? It suggests that the cart is pulling the horse and that the concrete arises out of the abstract, the known out of the unknown. When the physicist lapses into metaphysics he is apt to leave his terms undefined.

Of the remaining books before us we may briefly say that Prof. Mie's is a French translation of a German pamphlet recently noticed in these columns, that M. Lémeray traces the history of the rise and fall and ultimate extinction (as he seems to consider it) of the idea of the "ether," and that Dr. von Horvath has thought it well to try to give a new presentation of the restricted principle of relativity.

E. CUNNINGHAM.

Principles of Spectacle Design.

Handbuch der gesamten Augenheilkunde. Begründet von A. Graefe und Th. Saemisch, fortgeführt von C. Hess. Herausgegeben von Th. Axenfeld und A. Elschnig. Dritte, neubearbeitete Auflage. *Die Brille als optisches Instrument.* Von Prof. Dr. M. von Rohr. Dritte Auflage. Pp. xiv+254. (Berlin: J. Springer, 1921.) In Germany, 66 marks; in England, 132 marks.

SINCE the first edition of this work appeared ten years ago, the design of spectacles has undergone important developments which are attributed by the author to the increased competition of large specialist manufacturers, to the interest of ophthalmologists and technical scientific workers, and to recent war experience.

The work is worthily dedicated to Allvar Gullstrand, upon whose optical treatment of the subject the theoretical portions are based, and more particularly those sections concerned with the eye in motion. It deals in a thorough and comprehensive manner with the comparatively simple geometrical principles involved in the design of spectacles for the correction of abnormal vision, but, as is clearly stated in the preface, it does not enter the sphere of the optical computer to whom the practical design is entrusted.

Those who are interested in the theoretical problems of spectacle design will find in this work a clear exposition of most aspects of the subject. The formulæ as well as the diagrams can be relied upon, as they are particularly free from errors. An introductory section deals with spectacles of various materials for special purposes. Section I. is devoted to anastigmatic lenses for both fixed and moving eyes. Section II. deals with astigmatic lenses, under which are included the various toric forms and combinations. In Section III. chromatic aberrations are considered, and apparent aberrations in the image space resulting from vision through spectacles are discussed in the concluding section. Although excellent source, name, and subject indexes are provided, there is unfortunately no index of the symbols employed. The systematic historical index of the first edition has been dispensed with, as the information is included under the various subject headings.

Nearly one-half of the text is devoted to historical references which increase the general interest of the work. As the author states in his preface, the desire to recognise the true inventor lies close to his heart. The task is a difficult one, and, if the author has failed in some respects, it may be attributed to a too ready use of German sources of information. The historical notes do not extend much beyond 1917, although, according to the title-page, the edition dated 1921 is stated to have been newly revised. Indeed, there is only one reference as recent as 1920. An English author is pilloried (p. 114) for the absurd accuracy of certain numerical data, but the author himself, in many instances records to within 1/1000 mm. ocular dimensions that are comparatively indefinite.

There is a tendency throughout the work to sacrifice clearness to generality. Spectacles, for example, are inadequately defined as "optical instruments that can be carried continuously before the eyes," the object being not to exclude extreme cases such as protective glasses for stone-hewers, spectacles for drivers, and those in which use is made of mica, horn, and other substances. But the reader will find more in this book by Dr. M. von Rohr for warm approval rather than for criticism.

JAMES WEIR FRENCH.

Our Bookshelf.

A Manual of Determinative Mineralogy. By Prof. J. Volney Lewis. Third, revised and enlarged edition. Pp. v+298. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 16*s*. 6*d*. net.

WE have here an excellent guide to the recognition of mineral species. It is not intended to supersede the use of a standard work on mineralogy, but to train

a student to acquire a first-hand knowledge of minerals and their distinguishing characters and ultimately a facility in identifying the commoner species at sight. There is a general classification occupying more than 130 octavo pages based on physical characters, especially streak, colour, and hardness, in the order named. After a rather full account of blow-pipe and other convenient chemical tests, including some which are not commonly employed in this country, there is another classificatory table of 70 pages constructed to assist in the identification of minerals by this means. This is followed by a third table based on the crystalline system and hardness. Perhaps greater stress might have been laid on specific gravity, the determination of which is frequently one of the most rapid means of "running down" a doubtful mineral. Also no mention is made of the use of a permanent horseshoe magnet with special adjustable poles by the help of which the comparatively weak magnetic character of minerals like monazite can be easily recognised even in the field. J. W. E.

(1) *Botany for Students of Medicine and Pharmacy.* By Prof. F. E. Fritch and Dr. E. J. Salisbury. Pp. xiv+357. (London: G. Bell and Sons, Ltd., 1921.) 10*s.* 6*d.* net.
(2) *Junior Botany.* By T. W. Woodhead. Pp. 210. (Oxford: Clarendon Press, 1922.) 3*s.* 6*d.* net.
(3) *The Elements of Vegetable Histology.* By Prof. C. W. Ballard. Pp. xiv+246. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 18*s.* net.

(1) Prof. Fritch and Dr. Salisbury have prepared an elementary text-book, which is stated in the preface to be for the use of students of medicine and pharmacy. A large number of new figures of plant structures are produced, and many of them will form a useful addition to botanical illustration. A few, however, such as Figs. 69 and 71, are too diagrammatic, sketchy, or ragged to be desirable for elementary students, and of course they are of no use for any other purpose. The book begins with the plant as a whole, using the Shepherd's-purse as type. It goes on with several chapters on the various plant organs and their functions. The chapter on plant cells concludes with an account of protoplasm in colloidal terms. Growing points, tissues, cell contents, and the structure of roots, stems, and leaves are then carefully treated, followed by physiology and the study of types. The book ends with a chapter on heredity and evolution, and an appendix dealing with reagents and methods. It covers adequately the syllabus for medical students and is one of the best we have seen for this purpose, but it is questionable if a somewhat more biological and scientifically imaginative treatment of the subject would not be to the advantage of elementary botanical teaching.

(2) The second volume under notice is a neatly produced little book of more elementary character, and well illustrated, the 140 figures being new with one exception. It begins with a chapter on the garden stock, followed by condensed treatment of seeds and germination, roots and their function, the shoot and its physiology, hibernation and movement in plants. The second part deals with the structure and biology of the flower, including pollination, fruits, dispersal, etc. Every beginning student would find it useful, particularly for its studies of flowers and fruits, and the price is very moderate.

(3) The only features we can recommend in Prof. Ballard's book are the paper and binding, and the first and the last chapters, dealing with the structure and use of the microscope and its accessories. The body of the work is too crude, even for the pharmacy students for which it is intended, to deserve the name of botany. A single quotation from p. 122 will be sufficient to indicate how many errors can be packed into one sentence. "Communication between the various cells forming a tracheid is effected by means of pores in the vessel walls." The illustrations can only be characterised as for the most part very poor. Fig. 29 is intended to illustrate mitosis, and is stated to be "modified" from Strasburger's text-book. The drawings are almost caricatures. They show centrosomes where none exist, and the name "polar bodies" is given to them! It is a disservice to botanical science to publish a book of this character. R. R. G.

The Autonomic Nervous System. By Prof. J. N. Langley. Part I. Pp. viii+80. (Cambridge: W. Heffer and Sons, Ltd., 1921.) 5*s.* net.

THE present small volume gives a very useful summary, clearly and concisely written, of the present position of our knowledge of the subject of which it treats. The author divides the peripheral nerves into somatic and autonomic, and the latter into sympathetic (thoracico-lumbar, to all regions of the body), enteric (plexuses of Auerbach and Meissner), and parasympathetic, which is again divided into tectal (or ocular, supplying the sphincter of the iris and the ciliary muscle), bulbar (alimentary canal from nose and mouth to large intestine, with appendages, including the lungs), and sacral (lower part of large intestine, bladder, and external genitals). The several chapters deal with the divisions of the autonomic system and nomenclature; the general plan of origin and of peripheral distribution; the nerve fibres of the autonomic system; the specific action of drugs on the sympathetic and parasympathetic systems; and the tissues innervated. Each chapter is followed by a bibliography of important papers and by a series of notes.

First Course in the Theory of Equations. By Prof. L. E. Dickson. Pp. vi+168. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 8*s.* 6*d.* net.

THE introduction to the Theory of Equations contained in this volume is wide enough to cover the needs of all except those who aspire to become mathematical specialists. The methods throughout are strictly elementary, the treatment reaching the algebraic solution of cubic and biquadratic equations without any reference to substitutions or group-theory. Useful chapters on determinants and elimination are included, while another one deals with elementary properties of symmetric functions. The book contains a severe course of computation within the scope of its subject-matter, and a considerable proportion of the abundant examples are numerical in character. Two subjects avoided by most writers of elementary

text-books are discussed in a satisfactory and convincing way: (1) the impossibility of trisecting an angle, and (2) the construction of a regular polygon of seventeen sides, by the methods of Euclidean geometry. Prof. Dickson's book possesses all the merits of an excellent text-book, and it is to be hoped that its circulation will be a wide one.

Department of Scientific and Industrial Research: Fuel Research Board. A Handbook on the Winning and the Utilisation of Peat. By A. Hausding. Translated from the Third German Edition by Prof. Hugh Ryan. Pp. xxiii + 506. (London: H.M. Stationery Office, 1921.) 30*s.* net.

AN account of some processes for the utilisation of peat, particularly as a fuel, with references to German patents is given in the volume under notice. The mechanical details are better dealt with than the chemistry, which is often ludicrously inaccurate. The translator, indeed, often remarks on the latter point, and on the inaccuracy of the calculations, but makes no attempt to put things right. Some of the illustrations (*e.g.* Figs. 16, 46—which seem to be repeated in 54, 68, 69, 71, etc.) are very poorly reproduced. In spite of obvious defects the book contains a large amount of practical information not otherwise available in English, and will be of value to those interested in peat utilisation. An appendix, giving a reasoned account of the complete failure of some recent schemes, would have been instructive. The statistical information should be compared with that contained in the Final Report of the Nitrogen Products Committee, which is probably more accurate.

The Petroleum Industry: A Brief Survey of the Technology of Petroleum based upon a Course of Lectures given by Members of the Institution of Petroleum Technologists on the occasion of the Petroleum Exhibition, Crystal Palace, 1920. Edited by A. E. Dunstan. Pp. vi + 346. (London: The Institution of Petroleum Technologists, 5 John Street, Adelphi, n.d.) 14*s.* 6*d.*

THE petroleum industry is of peculiar interest and importance to the British Empire, and all readers of NATURE will welcome the appearance of the present volume. The series of lectures by experts have been carefully co-ordinated, and the result is very readable. All phases of the industry, from the prospecting for oil to the various uses of the finished products, are treated in a way which is a model of lucidity combined with accuracy of detail, and the book cannot fail to be of interest both to the specialist and to the general reader. The illustrations are particularly good. In the opinion of Sir Frederick Black "oil is not likely to supplant coal, but should supplement it"—a wise counsel.

Town Gas Manufacture: A Practical Introductory Treatment of the Equipment and Processes of an Average Gas Works, for Students, Junior Gas Engineers, and others connected with Gas Works. By Ralph Staley. Pp. xii + 108. (London: Sir I. Pitman and Sons, Ltd., 1922.) 2*s.* 6*d.* net.

THE scope of this book is sufficiently indicated by its title and sub-title. The accounts of the manufacture of gas coal and water gas, including purification, are brief but clear, and the illustrations are good. There is mention of "great pressure setting up heat" in stacks of coal (p. 6), and "high heats" (pp. 81-82), meaning high temperatures. The account of the reaction in the gas producer is out-of-date, while washing with anthracene oil might have been mentioned as a method of removing "naphthalene, that mysterious bugbear." The fact that carbon monoxide is dangerously poisonous is also worthy of mention to junior gas engineers. The book should be very interesting to students of chemistry as well as to those intending to enter gas works.

A First Book of Chemistry for Students in Junior Technical Schools. By Dr. A. Coulthard. Pp. viii + 156. (London: Sir I. Pitman and Sons, Ltd., 1922.) 4*s.* 6*d.* net.

DR. COULTHARD'S book has some features which distinguish it from the scores of "elementary" or "junior" text-books which have appeared in recent years. It is quite up-to-date in its information; the scope is limited but is still sufficient to give a good view of the fundamental laws of chemistry, although the atomic theory is not included, the book finishing with equivalents. In connection with class work and practical work (over a hundred good experiments are described) the book should be found useful, and it may be recommended for use in junior classes. Ten years ago a book of this size would have sold for two shillings at the outside, but the price is probably reasonable nowadays.

Manuel de parfumerie. Par I. Lazennec. (Bibliothèque Professionnelle.) Pp. 281. (Paris: J.-B. Baillière et Fils, 1922.) 8 francs.

M. RENÉ DHOMMÉE is editing an encyclopedia of 150 volumes on "travail national," which is intended for French artisans. The idea is good, and corresponds in many ways with that of the "Life and Work" Series now being published by Messrs. Macmillan. The scope of the book is similar to that of Parry's "Perfumes," recently noticed in NATURE, but is not quite so full on the scientific side. The technical processes are described in detail, with illustrations, and there are numerous recipes (which are not given by Parry). The book should fulfil its object, and we wish the editor success in his enterprise.

Oils, Fats, and Fuels. By T. Hull. Pp. viii + 143. (London: Blackie and Son, Ltd., 1921.) 3*s.* 6*d.* net.

A VERY elementary account of the subject suitable for students in technical schools and classes will be found in this book. The chemistry of the materials and processes are not dealt with, formulæ and equations being purposely omitted. There is no index. On p. 128 the composition of "modern coal gas" is given as containing only 8 per cent. of carbon monoxide and 3·5 of "oxygen, nitrogen, etc." This must refer to genuine coal gas and not to the "modern" variety. No mention of fat hardening is made.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Geology and the Nebular Theory.

THE literature of geology has grown so immense that no man can be familiar with all of it, particularly when it refers to another continent than one's own, yet it comes as a surprise to a Canadian to find eminent Old World geologists still referring to the nebular hypothesis as an established fact of geological history. A few weeks ago Prof. J. W. Gregory suggested that life began on mountains, since these were the first parts of the earth's crust to cool to a suitable temperature, and more recently Prof. Joly, in discussing the age of the earth, assumes the truth of the nebular hypothesis, though he admits that "there was indeed some scanty sedimentation in Archæan times."

Probably no country includes a larger area of Archæan rocks than Canada, and several parts of the area have been studied as carefully as possible because of their importance as mining regions, yet no evidence of a hot earth has been found. The Huronian rocks of cobalt include a glacial deposit which is known to have covered many thousands of square miles. The Sudbury or Timiskaming Series, next in age, consists almost entirely of sediments, such as boulder conglomerates which may be glacial, arkosi with unweathered feldspars, and graywacke with seasonal leanding. Near Sudbury the series has a thickness of more than 20,000 feet.

The oldest rocks of all are the Keewatin and the Grenville Series, the former consisting mainly of volcanics but including thousands of feet of sedimentary gneisses and of "iron formation"; the latter is made up wholly of sediments, reaching a thickness of more than 50,000 feet in places and containing immense deposits of limestone, as well as much carbon in the form of graphite.

It might be thought that the Keewatin lavas imply a hot condition of the earth, but as a fact most of them exhibit pillow structure, showing that they were poured out into water. Liquid water existed over many thousands of square miles, and probably the temperature was low enough for the life of algæ and perhaps of primitive animals, as suggested by the carbon and limestone. The rocks of this most ancient known geological period do not indicate a higher temperature than that of later times.

It is probable, however, that those geologists who think of the earth as hot in Archæan times have in mind the granites and gneisses which underlie the most ancient sediments, the Laurentian rocks of Canada and similar plutonic rocks of other countries, which undoubtedly are of eruptive origin, and have been described as part of the original crust of the molten earth. In reality the Laurentian batholiths are far younger than the sediments and volcanics of the Keewatin and Grenville which they have invaded, and a similar welling-up of plutonic batholiths has occurred at numerous times in the later history of the world, and is perhaps still taking place beneath great ranges of youthful mountains like the Andes and Himalayas.

The coast range of British Columbia, 1100 miles long and 100 broad, consists of just as characteristic batholithic rocks as the Laurentian, but is of Jurassic age, and the Andes, which are still younger, appear to be largely of the same character. Granite and gneiss may be of any age, and do not imply a cooling earth as some have supposed. We find greater areas of such plutonic rocks in the most ancient geological periods simply because they have been exposed to denudation for a longer time, and so have been more widely uncovered.

The conditions found in the Archæan of Canada are repeated in Brazil, India, and Scotland, and probably other countries of which the present writer has no personal knowledge. The oldest rocks in the world are sedimentary and indicate temperatures like those of later times. If the earth was ever a molten sphere, there is no evidence of this condition in the geological record, and geologists should not cling to an outworn theory which the astronomers themselves have largely given up. In the planetesimal theory a method of world building has been provided which permits of a cold surface from the beginning, and fits far better with the known geological facts than the nebular theory.

A. P. COLEMAN.

University of Toronto, Toronto, Canada, May 16.

Species and Adaptations.

MR. BATESON'S address to the American Association at Toronto last December, which was published in NATURE of April 29, exhibits features of the same kind as those which were evident in his address to the British Association in Australia in 1914. In the Australian address he maintained that the effect of the discoveries and investigations in recent years in the phenomena of heredity and variation was greatly to increase the difficulty of understanding the origin of any characters which were new in the proper sense of the word. He went so far as to suggest that all characters which have appeared in the course of evolution may have been present in the protoplasm or nuclear structure of the original unicellular forms from which later forms, including man, have descended, all apparently new characters having been due to loss of inhibiting factors and segregation of various simpler combinations from the original complex. Now Mr. Bateson again declares himself an agnostic with regard to the evolution of species, and in spite of all modern discoveries, or because of them, states that we are farther than ever from any satisfactory explanation of the evolution of a new species, or of two or more species, from a single ancestral species.

Mr. Bateson admits that plenty of Mendelian combinations would in nature be given specific rank, and then proceeds to state that the topic of evolution is now dropped in genetical circles. He then illustrates the rule of silence on this favourite subject of a former generation by devoting the rest of his discourse to it, only to lead up to the conclusion that specific difference probably "attaches" to a base of which we know absolutely nothing at all. Our faith in evolution, Mr. Bateson declares, is unshaken; our doubts are merely as to the origin of *species*.

Now I have no intention of stating in opposition to Mr. Bateson that our present knowledge fully explains the origin of new species; I wish merely to offer some criticisms of the difficulties which he describes. In the first place, I dislike the expression "faith in evolution." I do not share the distrust in facts and reasoning which is now in vogue as a reaction against the excessive confidence of the nineteenth century. Evolution is a question of science, of verifiable facts and sound reasoning, and has nothing to do with faith. Mr. Bateson himself in another paragraph

states that we have absolute certainty that new forms of life, new orders and new species, have arisen on the earth. The explanation is the difficulty, but we have ample evidence that organisms, whatever their characters, are only produced by reproduction from parents.

One is tempted to conclude that Mr. Bateson attaches some mystical meaning to the word "species." He says we have no reason to suppose that any accumulation of characters of the same order as those met with in genetical experiments would culminate in the production of distinct species. According to him there is some underlying base which is specifically distinct and bears the characters. I fail to see that this idea has any scientific meaning or validity. What is this base? In science we must regard things and phenomena objectively. We distinguish species by characters, just as we distinguish all objects by their qualities. For example, we have the familiar example of single comb and rose comb in fowls. We cannot have singleness and rose-ness without the comb that exhibits these characters. If they occurred in nature, excluding crossing or hybridisation, they would be specific characters, at least in company with other differences they might be. Is the comb then the base? The comb must have some character and shape, and thus we cannot have the comb without a character. We can have the entire absence of comb, as in the allied genus Phasianus; and so with all other characters. This idea of a specific base distinct from specific characters seems merely false metaphysics. How can we conceive of an organism without characters, or characters without an organism? Perhaps Mr. Bateson means that unit characters such as those which can be transferred in Mendelian crosses might all be taken away, and still an organism would be left with non-Mendelian characters. What are these characters? He does not tell us. We have cases of the absence of pigment in, *e.g.*, a bird, then the feathers are left. We may have an organism without feathers, and then the skin is left. We can scarcely have an organism, at any rate a vertebrate, without a skin. On the other hand, we may have factors, whatever their nature, which in the absence of one or more other factors produce no visible character, as in the cases of white varieties of animals and plants which, when bred together, produce coloured offspring. It has been shown that there are several kinds of white varieties or races, the distinguishing characters of which are invisible. Perhaps Mr. Bateson means that species were originally distinct in this way, separated by characters which were non-apparent.

Mr. Bateson insists on the rarity of the occurrence of new dominants under observation in experimental breeding, although new recessives, that is, the loss of particular characters from a combination, are common enough. Even in Drosophila few new dominants have been seen, and none of these could be expected to survive under natural conditions. He further states that in tracing the origin of our domesticated animals and plants we can scarcely ever point to a single wild species as the probable progenitor. Now it seems to me that there is very good evidence that all our breeds of domesticated fowls have descended from *Gallus bankiva*, and in the numerous existing breeds there are many dominant characters which are not present in the wild ancestral form, *e.g.* the dominant white of the White Leghorn, and the rose comb. Mr. Bateson says he cannot imagine such a new dominant character being produced. But surely it is evident that they have been produced in the succession of generations of domestic fowls. Mr. Bateson's difficulty seems to be merely that we do not know how they came into existence. We can, however, scientifically form the conclusion that they originate by some change or development in the chromosomes, not directly dependent on any corresponding external stimulus.

Another reason which Mr. Bateson gives for his scepticism is that the chief attribute of species is that the product of their crosses is frequently sterile. This seems on the face of it illogical. If the sterility is only frequent it follows that there are many cases in which such sterility is absent. In that case, as there are many species which produce fertile offspring, the sterility of species hybrids cannot be the "chief attribute" of species. It is neither a universal nor necessary characteristic, and all we can say is that we do not know how it arises in certain cases. John C. Phillips in America crossed three wild species of duck (*Anas boscas*, *A. tristis*, and *Dafila acuta*) and found the progeny fertile. Bonhote has published the results of numerous similar experiments in this country. The various species of Bovidae also are stated to be fertile *inter se*.

I find it very difficult to understand Mr. Bateson's reasoning on this subject. He states in one place that the fact that hybrids between species are by no means always sterile is a commonplace of everyday experience, and then a little farther on, insists that until the production is witnessed of an indubitably sterile hybrid from completely fertile parents which have arisen from a single common origin, we have no acceptable account of the origin of "species." The two statements contradict each other. Interspecific sterility may be very mysterious, but it has nothing to do with the origin of these species which do not exhibit this sterility. Moreover, there is evidence of the occurrence under observation and experiment of new varieties which are more or less infertile with one another. *Œnothera gigas*, a mutant from *O. Lamarckiana*, shows a great degree of sterility when crossed with other mutants from the same species, and two mutants of Drosophila in Morgan's experiments are almost completely sterile with one another.

It is not very surprising that genetical researches of the Mendelian kind have not thrown much light on the occurrence of variations and mutations, for except in the cases of Œnothera and Drosophila they have usually consisted in analysing by crossing experiments the hereditary factors already present, instead of breeding many generations from a single form and studying the variations that occur. To my own mind, there is no proof that the numerous breeds and varieties of domestic fowls, all descended almost certainly from the single species *Gallus bankiva*, differ in their essential nature from groups of closely allied species and varieties in a natural state.

The feeling, however, that chiefly prompts me to comment upon Mr. Bateson's Toronto address is one of protest against the implied disparagement of those who have not ceased to discuss evolution. There is more in evolution than the origin of species. Mr. Bateson himself has contributed largely to the proof that the distinctions between species have little or nothing to do with adaptation, but at the same time he has failed to realise the true nature and importance of adaptation in itself. In his address he makes no reference at all to adaptation, or to the relation which it bears to recapitulation in ontogeny, one of these "academic problems of morphology" which were discussed with such avidity when both he and I were young, and which he relegates with such confident assurance to the limbo of obsolete things. Yet he writes of the older time: "Regardless of the obvious consideration that 'modification by descent' must be a chemical process, and that of the principles governing that chemistry, science had neither hint nor surmise nor even an empirical observation of its working."

One would almost suppose that Mr. Bateson was a bio-chemist. But how much chemistry is there in the analysis of Mendelian factors, or the identification of spots in chromosomes which represent particular genes? The suggestions of the nature of the "chemical process" have come from the physiologists and from those who, without ignoring the methods and discoveries of genetics, have not ceased to discuss evolution and adaptation. It is true that some geneticists have discussed the question whether factors for colour might be chemical compounds reacting on each other, but they have not explained how chemical compounds such as enzymes and chromogens could be contained in separate chromosomes and segregate from each other in the reduction divisions of gametes. I do not remember any case in which "modification by descent," that is the loss or gain of a unit character, has been shown by geneticists to be due to any chemical process. The latest results of the American investigators concerning the localisation of genes in the chromosomes, concerning which Mr. Bateson states that all his scepticism has been removed, are purely morphological.

All the progress that has been made in our knowledge of unit characters and of specific characters has tended to exhibit more and more clearly the difference between such characters and adaptational features. It is seldom that an adaptation is confined to a single species, and it is impossible to perceive any connexion between mutations or unit characters and the relation of adaptations to function and external conditions. One great event in the evolution of both animals and plants was the adaptation of the descendants of aquatic forms to terrestrial and atmospheric conditions. In the case of animals, we have, in the metamorphosis of Amphibia and the embryonic development of higher vertebrates the recapitulation of this transition from aquatic organs of respiration to atmospheric organs, not by conversion but by substitution. It is certain from this evidence that the change was perfectly gradual and continuous, and parallel to the gradual change of conditions and mode of life. Recapitulation in this case, however ancient a subject it may be, is an obvious fact, and nothing that the geneticists have discovered throws any light on it, or diminishes its importance. It is no use dismissing it as early Victorian. The question is, have the recent, much vaunted discoveries explained it, or have they anything to do with it? Variations in wings, eye colour, etc., of flies bred in milk-bottles are important in their own sphere, but they throw no light on the annual growth, denudation, death, and recrescence of the antlers of a stag, or on the remarkable relation between these processes and the hormones from the gonads. The origin of species is a very important problem, but it is not the whole, or the most important part, of evolution. The origin of adaptations is not the same problem as the origin of species, and the methods of modern genetics have very little bearing upon it. Mr. Bateson's address suggests that he has not yet realised the difference between the two problems, or paid serious attention to modern physiological knowledge bearing on functional adaptation. The phenomena of recapitulation, so closely associated with adaptation, imply wherever they occur a continuity in the evolutionary change of which the adaptation was the result, and these phenomena are quite incompatible with the discontinuity which is characteristic of non-adaptive variations, and which is the cardinal principle of Mendelians and mutationists.

35 Wavendon Avenue, Chiswick, W.4.

Evolutionary Faith and Modern Doubts.

No one can have read without interest Dr. Bateson's admirable address on evolution published in NATURE of April 29. While Dr. Bateson's reputation is justly high and his views necessarily command respect, it must be admitted that some of his arguments are very difficult to follow. When, for example, he says that "the conclusion that species are a product of a summation of variations, ignored the chief attribute of species, that the product of their crosses is frequently sterile in greater or less degree," I am frankly puzzled. The proposition is certainly not self-evident. If a sword and its scabbard are bent in different directions, it will happen sooner or later that the sword cannot be inserted, and the result will be the same whether the bending be effected by a single blow, or whether it be, in Dr. Bateson's words, "a product of a summation of variations." Is this illustration inapt? The sword and its scabbard are the homologous chromosomes. These presumably have to co-operate to produce the somatic cell of the hybrid, and their co-operation might be expected to require a certain resemblance, but for the production of sexual cells they must do more, they must conjugate; and for conjugation it is surely reasonable to suppose that a much more intimate resemblance would be needed.

We might, therefore, expect, on purely theoretical grounds, that as species and genera gradually diverged, it would be increasingly difficult to breed a hybrid between them; but that, even while a hybrid could still be produced, a fertile hybrid would be difficult or impossible, since the cells of the germ-track would fail to surmount the meiotic reduction stage, when the homologous chromosomes conjugate. This is exactly what happens: the cells go to pieces in the meiotic phase.

It would even seem that the argument is exactly contrary to Dr. Bateson's statement of it: it seems easier to imagine sterility arising from a gradual modification, spread over a length of time, and involving many chromosomes, than from the half-monstrous variations chiefly studied by Dr. Bateson and his school, variations which appear to affect only a few chromomeres, and those by loss alone.

Now I certainly cannot pretend to much or special knowledge, either in genetics or cytology. But I would ask Dr. Bateson in all humility whether there is any difficulty involved in this simple solution of his problem. Very likely there is, but he does not indicate it.

C. R. CROWTHER.

2 Mutley Park Villas, Plymouth.

Transcription of Russian Names.

IN NATURE of May 20, p. 648, is published a letter from Maj.-Gen. Lord Gleichen, who raises objections to Prof. Brauner's suggestion (NATURE, April 29) that we should adopt the Czech transcriptions for the names of Russian men of science.

The argument that there are typographical difficulties is surely a very small one, since NATURE and other journals (*e.g.* that of the Chemical Society) already employ letters with diacritical marks in writing the names of Czech and other authors. Whilst diacritical marks are undesirable for place names on maps, the same need not apply to the names of persons.

The main points raised by Prof. Brauner in support of his suggestion, remain unchallenged, and in addition to these it may be mentioned that the Czech language is phonetic and Russian names can thus be accurately pronounced according to it.

Further, it may be confidently anticipated that the men of science and scientific institutions of the Czecho-Slovak republic will accomplish much in the way of scientific advancement in the future, and consequently will receive more adequate notice in British journals than has hitherto been the case (compare Prof. Brauner's own resumé of "Science in Bohemia" in NATURE, May 13).

Finally, many Russian authors now publish in Czech journals and consequently use the Czech transcriptions for their own names.

May 24, 1922.

Immediate Solution of Dynamical Problems.

A DISCUSSION is submitted here in the manner called elementary, where the theorems of the gravitation of a sphere are proved for any portion of a spherical surface, such as a bowl, before proceeding to the result for a complete sphere (see letter by Prof. Andrew Gray in NATURE, May 20, p. 645).

Consider the potential (Fig. 1) at P, dU, and attrac-

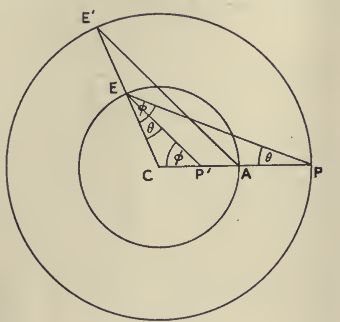

FIG. 1.

tion to the centre, dF, of a small element dS at E, of the surface of a sphere, centre C and radius $CA=c$, taken of superficial density σ, g/cm², with G the gravitation constant. Then

$\frac{dU}{G\sigma}=\frac{dS}{EP}$, with $EP=CE\cos\phi+CP\cos\theta$, so that, with $CP=r$, and P′ the inverse point to P in the sphere, $CP'=r'=\frac{c^2}{r}$, $\frac{dS}{EP}=\frac{dS}{EP^2}(CE\cos\phi+CP\cos\theta)$

$$=CE\frac{dS\cos\phi}{EP^2}+CP'\frac{dS\cos\theta}{EP'^2}\quad\left(\text{because}\quad\frac{CP}{CP'}=\frac{EP^2}{EP'^2}\right)$$

$$=CE\,d\omega+CP'd\omega'=c\,d\omega+r'd\omega'=c\,d\omega+\frac{c^2}{r}d\omega',$$

reckoning the solid angles $d\omega$, $d\omega'$ subtended by dS at P, P′ as positive when the aspect of the surface is the concave side.

Then by summation over any finite portion of the spherical surface,

$\frac{U}{G\sigma}=c\omega+r'\omega'$, not restricted to the spherical bowl result in Maxwell's "Electricity and Magnetism."

And for F, the radial component acting along PC of the attraction at P,

$$\frac{dF}{G\sigma}=\frac{dS\cos\theta}{EP^2}=\frac{CP'}{CP}\frac{dS\cos\theta}{EP'^2}=\frac{r'}{r}d\omega'=\frac{c^2}{r^2}d\omega',\ \frac{F}{G\sigma}=\frac{c^2}{r^2}\omega'.$$

These two or three lines of geometry can thus replace some pages of analysis in Maxwell's "Electricity and Magnetism."

For a complete sphere, and P inside, $\omega=4\pi$, $\omega'=0$, $\frac{U}{G\sigma}=4\pi c$, $F=0$, and P outside, $\omega=0$, $\omega'=4\pi$, $\frac{U}{G\sigma}=4\pi r'=\frac{4\pi c^2}{r}$, $\frac{F}{G\sigma}=\frac{4\pi c^2}{r^2}$; the well-known theorems for a complete spherical shell, and thence for a solid sphere, given first by Newton in the "Principia" (1, 41), and of pioneering interest in justifying his theory of gravitation for a body, like an apple, brought from the moon down to the surface of the earth.

A recent article by Florian Cajori, on Newton's discovery of Gravitation, in the *University of California Chronicle*, April 1922, is worth the attention of Prof. Andrew Gray, in its bearing on his own historical reflexions on the importance of the attraction of a sphere in Newton's theory of universal gravity.

The further theorem, that the mean potential over the sphere of any body M outside the sphere is equal to the potential of M at the centre, is obvious by transferring an element of M at P to the other end of the vector PE. Or if M is inside the sphere, the mean potential over the surface is M/c.

In hydrodynamical analogy, the flux across any surface fixed in an incompressible liquid is the equivalent of liquid supplied to the interior from outside, and so interpreting and justifying the theorem of Gauss, between the surface integral of normal force and the attracting body M, inside or outside.

In this way the precept of Poinsot can be followed, to examine the nature of things in themselves by direct vision, and not through a mist of equations and formulas.

G. GREENHILL.

1 Staple Inn, London, W.C.1, May 27.

Arabic Chemistry.

IN a manuscript in my possession of the "Rutbatu 'l-Ḥakīm" of Maslima ibn Muḥammad Abu 'l-Qāṣim al-Majrīṭī († 1004 A.D.) the author claims to have written the section on chemistry in the celebrated "Letters" of the Ikhwānu'ṣ-Ṣafā (Brethren of Purity), the well-known Encyclopædists of Islām in the tenth century A.D. I believe this fact to have been hitherto unknown, as it is not mentioned by Dieterici or Brockelmann nor by Shahrazūrī, all of whom give as the names of the authors of the "Letters" only the following five: Abū Sulaimān Muḥammad ibn Naṣr al-Bustī, Abu 'l-Ḥasan 'Alī ibn Hārūn az-Zinjānī, Abū Aḥmad an-Nahrajūrī, al-'Aufī and Zaid ibn Rifa'a.

Maslima al-Majrīṭī was an accomplished chemist, and his work the "Rutbatu 'l-Ḥakīm" was mentioned by Ibn Khaldūn in the "Prolegomena" to his history. Although much of the "Rutba" is, as Ibn Khaldūn observes, very enigmatical, yet there are certain passages in it of considerable historical interest to chemists. Two of these I give below.

1. "I took natural quivering mercury, free from impurity, and placed it in a glass vessel shaped like an egg. This I put inside another vessel like a cooking-pot and set the whole apparatus over an extremely gentle fire. The outer pot was then at such a temperature that I could bear my hand upon it. I heated the apparatus day and night for 40 days, after which I opened it. I found that the mercury (the original weight of which was ¼ lb.) had been completely converted into a red powder, soft to the touch, the weight remaining as it was originally."

2. [On the refinement of gold and silver.] "Silver alloyed with lead may be separated from the latter by placing it in a cupel made from bones (called the 'dog's head' or commonly the *kūraja*; it is a crucible made from burnt bones) and fusing it by means of a strong fire. The lead is removed and absorbed by the cupel and the fire makes manifest

the lighter portion of the alloy; the silver remains pure and free from base metal. Silver may be separated from copper in the cupel by continual addition of lead until it appears in a state of purity. . . . Gold may be purified from silver and copper in two ways. From copper alone it may be refined by the method used to purify silver from copper, namely, cupellation with addition of lead. If it is desired, sulphur may be added as well; this burns the copper and the gold remains pure. Gold may be refined from lead by the method used to refine silver from lead. The purification of gold from silver may be carried out in two ways, one by means of minerals and the other by means of salts. The former method is as follows: the gold alloyed with silver is beaten out into thin leaves and these are placed on a bed of a mixture of hæmatite and salt and covered with more of the same mixture followed by a layer of red clay. The whole is then heated in the oven known to men of science as the 'refining-furnace,' when the silver is absorbed by the earthy matter and the gold leaves are left pure, containing nothing but the most refined gold.

"This operation may also be carried out in a similar way by using alum and salt, or by means of baked clay. The clay is finely powdered and mixed with an equal amount of salt and the two well powdered again. The mixture is then spread in a layer on a layer of red clay. A gold leaf is then added, followed by another layer of the mixture of clay and salt, and so on until all the gold has been added. A covering layer of clay and sand is then placed on the top and the whole strongly heated, when the gold is purified and extracted from the silver. . . . This is the process known as <u>sh</u>ahīra [refinement] by the people of this art. Gold may also be separated from silver in the same way that it is separated from copper. The gold-silver alloy is mixed with a little copper and the mixture fused, with addition of red sulphur from time to time. The gold refines away from the silver and is left pure. The former method, however, is the more efficient.

"The silver which is removed from the gold in the process called <u>sh</u>ahīra may be recovered merely by the addition of mercury to the earthy residue. The mercury thickens and coagulates until it becomes like dough, and this is the sign [of the completion of the action]. When it has become like dough it is placed in a crucible over the fire and the mercury then volatilises away from the silver." E. J. HOLMYARD.

Clifton College, May 29, 1922.

The Notion of Asymmetry.

MODERN refinements in our ideas of atomic and molecular structure at once demand a more precise definition of what exactly is meant by molecular asymmetry. Whether this asymmetry be due to certain groupings around a particular atom, or to the structure of the molecule as a whole, such physical properties as optical activity or enantiomorphism must ultimately be shown to be definitely related to the electronic and nuclear arrangements in the molecule itself.

Langmuir has shown that substances with molecules possessing similar electronic environments closely resemble each other in many of their physical properties, and he calls this phenomenon isosterism, the substances themselves being denoted isosteres. In this brief discussion it will only be necessary to consider the application of this idea to the simplest case of stereoisomerism.

The molecule *Cabcd*, where *a*, *b*, *c*, *d*, are all different atoms or groups, is asymmetric. It exists in two stereoisomeric forms, one the mirror image of the other. The substance having this molecular structure may crystallise in two enantiomorphously related forms, and may rotate the plane of polarisation of light. Now let *d* be replaced by *c'*, where *c'* is an isostere of *c*. Such a molecule is now no longer asymmetric as regards the arrangement of its electrons, but is certainly asymmetric if we take into account the inner nuclei. If the rotation of the plane of polarisation of light is dependent entirely on electronic movements, such a substance may not be optically active, and it may not even crystallise in two forms. We have not sufficient data to decide this matter; but it is obvious that the application of this idea to the case of isotopic elements entering into combination might lead to some interesting investigations. We will only consider the substance $CH . SO_3H . Cl_{35} . Cl_{37}$, where Cl_{35} and Cl_{37} are the two principal isotopes of chlorine. This compound, like *Cabcc'*, is asymmetric as a whole, but so far as its electronic environment is concerned, the two stereo forms are identical.

Now this particular variety of di-chlor-methane-sulphonic acid must be formed to a certain extent in the ordinary preparation of the substance, and it would seem that its isolation could be effected, only if it *did* actually exist in two enantiomorphously related forms. From what has been said this seems rather unlikely, but still, an investigation in this direction would throw some light on the matter, one way or the other. THOMAS IREDALE.

University College, London.

The Evolution of Plumage.

MAY I be allowed to refer to some of the statements in the article on the Evolution of Plumage published in NATURE of May 20, p. 662.

(1) The writer (H. F. G.) states that in the case of ducks and penguins "the difference between their nestling coat and the final dress is enormous." In my paper on "The Nestling Feathers of the Mallard," I point out that the tail-quill protoptiles consist of a calamus, containing cones, a shaft and a distinct after-shaft, and especially that the barbules at the tip of the shaft in having hook-like cilia are more specialised than in some of the true metaptile feathers of the adult; hence it follows that feathers of the first nestling coat, instead of being simpler, may be more complex than true feathers of the adult coat.

(2) It is stated that in the emus the differences between the nestling feathers (protoptiles) and the feathers of the second and later generations "are reduced to a question of mere size." As the figures in my paper clearly show, the aftershaft of the feathers of the first generation is represented by a few simple barbs, whereas the aftershaft in the following generations is as long and as complex as the shaft.

(3) Owls and petrels are said to "have as thick and fluffy and long-lasting mesoptile coats as any penguin." In the case of the tawny owl the mesoptile coat is poorly developed and (in specimens I reared) shed soon after growth is completed—perhaps, like Pycraft, the writer of the article regards the feathers forming the first coat of true feathers in the tawny owl as mesoptiles; the feather figured in "A History of Birds" (p. 270) is not a mesoptile but a true (metaptile) feather. In a young petrel I received last autumn from Dr. Eagle Clarke, the mesoptile coat consists of simple feathers less than half an inch in length—in penguins the mesoptiles are complex and sometimes reach a length of four inches.

J. C. EWART.

The University, Edinburgh.

(1) Surely the coats differ, almost beyond recognition in penguins; even in ducks, in which the first dress does not consist only of tail-quills.

(2) The figures [diagrams] show clearly that the all-important fact has been missed, namely, that the so-called aftershaft or byfeather consists not only of a few simple barbs but also of a distinct shaft.

(3) Perhaps it will save matters if we read: Some owls and some petrels have as thick and fluffy and long-lasting mesoptile coats as some penguins, relatively of course. For example, if some nestling feathers of the shearwater measure 24 + 26 = 50 mm. in length, this does not prevent large penguins from wearing still longer and longer-lasting coats; nor is it incompatible with some small petrels having mesoptiles (they vary much according to position) less than half an inch in length.

Perhaps some genius, not too much hampered by facts, may still discover a "law," or equation by which the palæontological dates of various groups of birds can be deduced from the relative emanations of their successive nestling coats. H. F. G.

The Atomic Weight of Mercury from Different Sources.

THE successful accomplishment of separating the isotopes of mercury (NATURE, 106, 144, 1920; *Phil. Mag.* 43, 31, 1922) suggested an investigation to determine the extent to which samples of mercury from different sources might show the same atomic weight, *i.e.* the same density, which is to be expected only if the various minerals contain the isotopes in the same ratio.

Mercury obtained from the following minerals was investigated:—

	Mineral.		Geological Period.
1.	Cinnabar from	Almaden (Spain)	Silurian.
2.	,, ,,	Phalz (Germany)	Permian.
3.	,, ,,	Idria (Dalmatia)	Triassic.
4.	,, ,,	California (U.S.A.)	Cretaceous.
5.	,, ,,	Santafiora (Italy)	Eocene.
6.	,, ,,	Ras-el-Mah (Tunis)	Upper Eocene.
7.	,, ,,	Gölnicz (Hungary)	
8.	Calomel ,,	Terlingua (U.S.A.)	Lower Cretaceous.
9.	Mercury oxychloride,	Terlingua (U.S.A.)	Lower Cretaceous.
10.	Cinnabar, synthetic, unknown origin		

After reduction with iron and repeated distillation of the metal *in vacuo* the densities were measured by the method described in the previous communication. We found no difference in density exceeding the possible experimental error, which amounted to 2–6 in a million, corresponding to 0·0004–0·0012 in the atomic weight. Considering the very different geological and geographical origin of the mercury samples investigated we can conclude, with great probability, that the isotopic composition of mercury of terrestrial origin is the same.

The following numbers are the density data ($d_4{}^0$) found in the literature:—

13·5959 (Regnault, 1807).
13·5958 (G. de Metz, 1892).
13·5956 (Vincenti and Omodei, 1888).
13·5953 (Volkmann, 1881).
13·5938 (Marek, 1883).
13·5937 (Thiesen and Scheel, 1898).
13·5886 (Biot and Arago, 1816).

The considerable differences exhibited by several of these numbers do not exclude the possibility that mixtures of different isotopic composition were measured. From the above-mentioned investigation, however, we are justified in assuming the differences as most likely due to experimental errors.

The English Ph.D.

SOME time ago I had the privilege of listening to addresses by the heads of two prominent English colleges on the provisions for the English Ph.D. Quite frankly it was stated that this degree is intended to satisfy students from the Dominions and the United States. It is manifestly unfair to give an American, for example, as a result of his study a degree, like M.A., which is of little or no value in his own land.

Two fundamental mistakes, however, have been made which endanger the value of the English Ph.D. Perhaps this can be made clear by considering the matter from a purely practical aspect. The American undergoes the expense of his work for the Ph.D. primarily because it helps him to a better post than he would otherwise get. If his degree does not help him to earn his living it has no more than a sentimental value. When applying for his post, his degree is weighed by the faculty and other authorities. It is *their* opinion that determines the character of the university work for the Ph.D.

These people require evidence that the candidate has received what *they* consider to be the best training. In the first place, his degree must be from a place where his subject is well taught. For a post in geology the degree from a university where geology is represented by a distinguished professor is a valid claim, whereas one from a university with a less able geologist is of lower value. The English universities must recognise that the value of their Ph.D. depends on the distinction of their teachers and not on their antiquity or fame.

The general intellectual training of the man is a second factor. His degree must mean that he is imbued by the spirit of scientific research derived through contact with the leading investigators. This implies immediately that for the particular departments which the university decides to develop the Ph.D. instruction, it must have professors of the first rank. A general all-round training, at least in the man's particular subject, is also demanded. This implies that the student must spend his time at different universities. The man who has worked in physiology under Sherrington, Bayliss, Starling, and Langley is a better-trained man than one who has spent his whole three years with only one of them. The English system, however, seems to deny or discourage the principle of migration. Unless something like the German system of free migration is developed the English degree can never have a value equal to the old German one.

It is not necessary to discuss certain other regulations; they will lapse by their own failure. For example, one university has proposed that the student shall choose his problem of investigation at the beginning of his three years and devote himself mainly to following it under the guidance of the professor. Such a process would turn out a narrow-minded monk, and not the all-sided man of science of wide views that is demanded. Most of the regulations proposed by the universities are aimed at keeping out unfitted students—quite proper but minor considerations. In none of the discussions that I have heard has there been any conception of the more important matter of providing for the proper development of the scientific investigator with the gift of presenting his results to the world. Yet this is just what the American universities demand from candidates for vacant posts. What these provisions must be I will not attempt to indicate. They can be discovered only by careful inquiry into the causes of the success of some universities and the stagnation of others. E. W. SCRIPTURE.

Identification of a Missing Element.

IN two recent communications to the Paris Academy of Sciences (*Comptes rendus*, May 22), by M. A. Dauvillier and Prof. G. Urbain respectively, very definite conclusions have been reached as to the identity of celtium with the missing element of number 72 on the Moseley classification. This discovery is of special interest to British workers, since Moseley's last work dealt with this particular problem. Prof. Urbain adds a statement on the unpublished work of Moseley on the X-ray spectra of his preparations of the rare earths. In his paper M. Dauvillier announces the discovery of certain lines in the L X-ray spectrum of celtium which show that its atomic number is 72. An improved De Broglie photographic spectrometer was used, and the oxides of lutecium and ytterbium in a preparation of Urbain's were attached to the anti-cathode. The tube was run at a potential of 40 k.v., and nearly complete L-spectra of lutecium and ytterbium were obtained. In addition three lines of thulium were found and two feeble lines which were identified as the α_1 and β_2 radiations of celtium. These lines ($\alpha_1 = 1{\cdot}5618$ Å ; $\beta_2 = 1{\cdot}3194$ Å) fall in the correct places for the element of atomic number 72, between the corresponding lines of lutecium and ytterbium. The β_1 and γ_1 lines of celtium which might have been expected are coincident with the β'_2 and γ_3 lines of lutecium. Reasons are given why these lines of celtium cannot be due to any impurities, such as other rare earths.

The following is a translation of Prof. Urbain's paper in the *Comptes rendus*:

THE ATOMIC NUMBERS OF YTTERBIUM, LUTECIUM, AND CELTIUM.

"The results of M. Dauvillier's examination of my preparations containing celtium have a theoretical importance obvious to all who have followed recent scientific developments with regard to the chemical elements and their atomic structure.

"It is now unquestionable that the element of atomic number 72 is actually celtium. The atomic weight of celtium must therefore lie between 175 (lutecium) and 181·5 (tantalum). Characterised by two sets of spectral lines (arc and X-ray) and by the order of magnitude of its atomic weight, celtium has conclusively won its place among the chemical elements.

"Thus the problem of the constituent elements of Marignac's 'ytterbium' has been solved. The method of X-ray analysis is the most significant, and probably the crucial, test of a chemical element, and this method has confirmed the work I have done over a period of more than ten years on 'ytterbium,' using more difficult and probably less conclusive methods. Though I only succeeded in obtaining a partial separation, this was sufficient to permit the high-frequency spectra method to assign its atomic number to each of the constituents I discovered, namely, (neo-) ytterbium 70, lutecium 71, celtium 72.

"Now that these results are clear, I wish to outline a part of the history of these elements that has not yet become known to the scientific public. When I originally announced the discovery of celtium, Moseley's law of the atomic numbers was still unknown. After this law had been found it seemed evident that it should be possible to define the three elements of the ytterbium group by their X-ray spectra. Moseley himself put forward the hypothesis that celtium and the element with atomic number 72 were one and the same. On the other hand, Moseley, relying on the evidence of Auer von Welsbach, in his first lists of the elements had included two thuliums, while my experiments only permitted the existence of one.

"In order to settle this question, in June 1914 Ramsay and I visited Prof. Townsend's laboratory at Oxford, where Moseley was working. Our intention was to examine the different products of my separation of ytterbium by this young investigator's method, then unique.

"We found one thulium of atomic number 69, one ytterbium of atomic number 70, and one lutecium of atomic number 71. The spectra which Moseley obtained included only a few lines, and we could not find any corresponding to the element of atomic number 72. The first of these results was announced several years ago, but as the result of the researches of others. No claim of priority was possible, since Moseley himself was responsible for the publication of these results, and for this purpose had kept the necessary documents. But the war broke out before he had time to write his paper. He was among the first to enlist, and by great misfortune was killed at the Dardanelles.

"Sir Ernest Rutherford, who prepared the obituary notice of his pupil, wrote to me about these last researches of Moseley's, at which I had assisted. In the absence of precise data I thought I must forgo the publication of results that would rest on my memory alone.

"M. Dauvillier's discoveries complete the early results obtained at Oxford. They show that the negative result given by Moseley's method in the case of celtium was due only to the insensitiveness of the method, since the preparation examined by M. Dauvillier is the same as that used in Moseley's own X-ray tube."

Now that the missing element of number 72 has been identified, there remain only three vacant places of ordinal numbers—43, 61, 75—between hydrogen and bismuth in the Moseley classification of the elements. With the rapidly increasing perfection of technique of X-ray spectra and the use of powerful installations, it is to be anticipated that the missing elements should soon be identified if they exist in the earth. The law of the X-ray spectra, as found by Moseley, is an infallible guide in fixing the number of an element, even if present in only small proportion in the material under examination.

E. RUTHERFORD.

Recent Excavations at Stonehenge.[1]

By Col. WILLIAM HAWLEY, F.S.A.

THE arrangement of the stones at Stonehenge includes on the outside a circle of sarsen stones, which were originally thirty in number and were capped with lintels, forming a continuous ring round the top. Inside this circle is another of smaller stones, originally forty-three in number, but without lintels and of a different rock from those of the outer circle.

Within the second circle of small stones were five

[1] Address to members of the Portsmouth Literary and Philosophical Society on the occasion of a visit to Stonehenge on May 6, 1922.

trilithons of large blocks of sarsen. Two only remain standing and one stone of the third. They have lintels, but the lintels were not continuous and merely formed a cap to the two upright stones.

The trilithons are not arranged in a circle but take the form of a crescent or horse-shoe, as also do a series of fifteen small stones within them, similar to the others in the second circle. The smaller stones (or foreign stones) are from metamorphic rocks and have been brought from a long distance, but how or when has not yet been determined. Dr. Thomas of the Geological Survey considers the source of two kinds to have been the Prescelly Mountains in Pembrokeshire, where he found identical specimens. He considered that their deposition here by glacial action to be contrary to sound geological reasoning, and that their assemblage here pointed to human selection and conveyance. One sort is a porphyritic diabase, another is a rhyolite, both of which are extremely hard. Another sort is an argyllite resembling hard slate, but being perishable, no standing stone remains, though many pieces are found in the soil below the surface. All these stones appear to have been brought in a rough state and in naturally long slabs, which were afterwards dressed.

The sarsens had less far to travel, and there can be little doubt that they were brought from the Marlborough Downs, where there are still many boulders of them strewn over the land.

These big blocks or boulders are composed of siliceous granules, and were formed in the Bagshot sand of the middle Eocene, and were left behind when the sand around them was denuded in a geological change.

Before being conveyed here they were roughly squared by cleavage to lighten them, and after arriving they were neatly dressed, partly by picking with pointed flint tools and partly by crushing and grinding with mauls made of a very hard quartzite.

After standing here for about 4000 years they have naturally become greatly weathered, some more than others, depending upon where softer patches in their substance occur, so that it is only on the durable parts that tooling marks can be seen, but these are very clear where the surface has not been exposed, where the stones are protected below ground, and where the lintels fit upon the uprights.

For many years several of the stones were leaning dangerously and had to be propped, notably the four on the north-east and two on the east, all bearing lintels. H.M. Office of Works has had these stones set upright, and their bases are now firmly fixed in beds of concrete.

In this operation it was necessary to take down the lintels, and we were much impressed by the elaborate care that had been bestowed upon fitting them to the tops of the stones. Every lintel has two cup-shaped holes, which fit upon tenons projecting from the upright stones, so that each lintel has two holes and each upright has two tenons (except the trilithons which only require one tenon on each upright).

The fitting of the lintels to the tops of the stones had been done with such accuracy as to leave little doubt that they had been worked in unison and the lintel frequently tried on until a perfect fit had been accomplished. The same care was observable in the fitting of the ends of the lintels, as each one has a projection which fits into a recess in the next following it, locking them all together, and all this must have been done when the stones were upright and to ensure evenness of the tops all the way round.

These stones were irregular in their depth below the surface, the longest having 8 feet and the shortest 4 feet 6 inches below ground. The bases end in a blunt point, to facilitate movement when getting them into position. Most of them seem to have been brought to their places down an inclined plane cut in the solid chalk, but two cases were met with where they had been put in vertically. The pieces broken off the bases when pointing them were used for propping them whilst adjusting their position and before the soil was returned to the hole around the stone. A great many other pieces of stone had to be used, and these had to be sought at places a few miles from Stonehenge, as there is no stone in this neighbourhood. Wooden posts were used for a similar purpose, their holes being found below the stones and sunk about two feet in the chalk. The acquired stone was of two sorts, a glauconite and a ragstone, the former from Hurdcote near Wilton and the latter from Chilmark, a few miles farther west. The same quarries appear to have been used ever since, as similar stone is frequently met with in the British villages of the Roman Period, and we found that they had supplied all the stone for the building of Old Sarum. In this case a freestone had been used and not the rough slabs found here. The freestone occurs at a lower level, and is extensively quarried at the present day.

Finds of interesting objects have been remarkably few; indeed nothing of any special interest. The things found consist chiefly of rough flints used for dressing the stone and stone mauls, or hammer stones, of various sizes up to 43 lbs. in weight. Immense quantities of chips were knocked off by the masons. Those of sarsen occur at all depths, but those of foreign stone not lower than 30 inches, as they were put in last of all, and the building was probably a long, continuous work. The rubble below the surface, besides containing chips, yielded a few pieces of Bronze Age pottery, very small and foot-worn. The firm rubble had arrested the descent of these and also of small pieces of Roman Period pottery, and very occasionally a coin of that time. These were mixed with other things that had reached the rubble at every succeeding age down to the present time.

It is remarkable that the great number of people employed upon the construction of the place have left nothing behind them, for life in the Stone Age was not incompatible with a fairly high state of culture, as has been noticed in many instances. There was pottery of excellent design at the Temple of Tel Harkien at Malta, of Neolithic times, some of it being beautifully inlaid.

The use of this place has not yet been determined. Among ancient races religious and secular matters were intimately mixed, but this place could not have been for secular use, as apparently it was not inhabited. There are perhaps as many theories about Stonehenge as the stones which compose it, yet nothing is known with certainty about the nature of the place. It is trusted, however, that when the present research is finished some definite conclusion may be arrived at.

The place has been surrounded by a circular

earthwork and outer ditch. Also, within the earthwork there are round patches of chalk. These have been placed there to mark the sites of holes which were discovered two years ago. We have named them Aubrey holes after an investigator of that name who, in 1666, hinted at their possible existence, but did not find them. Only about half the number has been opened, but we have ascertained that there are fifty-six. They are evenly spaced at 16 feet apart, and there can be little doubt that they once held stones forming a continuous circle, older than the existing monument. The old circle stones would have been rough, undressed ones, and perhaps of about the date of Avebury. When the present monument was built it is possible that the rough stones were taken out and dressed and erected as the smaller stones now visible, as it is not likely they would have been wasted, and, moreover, their number corresponds nearly with that of the holes.

The empty holes appear to have been used for human interments, as nearly all of them contained cremated bones. Only a portion of the cremated remains of a body are found in each hole and in one instance only fourteen pieces of charred bone. The actual cremations must have been carried out elsewhere and the remains brought here for interment, for up to the present time no sign of a large fire has been met with; and the burning of only one body would require several tons of wood to calcine it thoroughly, and the quantity of black wood ashes remaining, being indestructible, would have been noticed. These interments occurred in Neolithic times, as chips were found amongst the debris in the holes, and in one instance an implement maker had thrown all his discarded chips into a hole.

Lately I have been excavating the ditch outside the earthwork. It was probably the first work done here, and from it I trust to get a continuous linking up of periods from the earliest to the latest. So far this work has not been very profitable, but has given a good result in showing that a very long time must have elapsed between making the ditch and rampart and the building of Stonehenge. It seems to have fallen into neglect, and was nearly silted up when Stonehenge was built. This is conclusively shown by finding the masons' chips only 14 or 15 inches below the surface in the rubble covering the silt, where they cease abruptly, the silt containing no trace of anything relating to Stonehenge. It is devoid of any objects beyond occasional small fragments of animal bone, but when the bottom is reached at 4½ to 5½ feet below the surface, flint chips discarded by implement makers are found in great quantities, but rarely an actual implement. Many staghorn picks used in the excavation of the ditch are met with, and the upper parts of antlers cut off and thrown away when the picks were made.

This season I am again excavating the ditch, and this time on the north-east, to find out if it was a continuous circle or whether the avenue was made at that time or later, when Stonehenge was built, for I am inclined to think that there were two distinct periods here—an early one, when the circle of stones stood round the rampart, and a later one when this Stonehenge was built, with a considerable interval between them.

The Sense of Smell in Birds: a Debated Question.

ORGANS of smell are present in birds as a class and are well developed in many species, but much doubt attaches to the nature and extent of their usefulness. The South American vultures and the petrels are noteworthy for the size of their olfactory chambers, and the Apteryx possesses a complicated nasal labyrinth and is peculiar in having its nostrils at the extreme tip of the beak. Yet even in cases like these the practical demonstration of a sense of smell is beset with difficulties, and the existing evidence is conflicting and largely inconclusive. It seems difficult, of course, to believe that the apparatus serves no purpose, especially where it is highly developed or is specialised along particular lines, but apart from the unsatisfactory quality of *a priori* arguments the alternative must be borne in mind that the organs may have some other function than a sense of smell of the kind with which we are subjectively familiar.

The sense of smell is notoriously acute in the majority of mammals. Although they are generally also well endowed with sight and hearing, it is by smell that they chiefly find their food and by smell that they receive the first warning of the proximity of enemies: the importance of approaching four-footed game upwind is a commonplace. In birds the case is obviously very different, for with them vision must certainly be given pride of place. Hearing, too, is very well developed in birds, and there is also often a delicate sense of touch—witness the bill of the snipe—and possibly some power of discriminating food by taste. It may be argued that a sense of smell would be less useful to birds than to mammals: the great distances from which some birds detect their prey seem practically prohibitive for any sense but vision, and the spaces of the upper air must form a much less favourable medium for scent than the ground winds on which mammals so greatly rely.

Like so many other problems of natural history, this question attracted the attention of Charles Darwin, and in "A Naturalist's Voyage Round the World" we read of the experiment which he made in a garden in Chile where twenty or thirty captured condors were tethered in a long row at the bottom of a wall. "Having folded up a piece of meat in white paper," he says, "I walked backwards and forwards, carrying it in my hand at a distance of about three yards from them, but no notice whatever was taken. I then threw it on the ground, within one yard of an old male bird; he looked at it for a moment with attention, but then regarded it no more. With a stick I pushed it closer and closer, until at last he touched it with his beak; the paper was instantly torn off with fury; at the same moment, every bird in the long row began struggling and flapping its wings. Under the same circumstances it would have been quite impossible to have deceived a dog." In the same place Darwin

refers to the well-authenticated experiments of a Mr. Bachmann with the American turkey-buzzard, another carrion-eating vulture and one in which highly developed olfactory nerves had been demonstrated by Owen. Portions of highly offensive offal were wrapped in thin canvas: the birds seemed unable to detect the food even when eating pieces of meat which were in some cases strewn on the outside of the package, but as soon as a small rent was made for them in the canvas the prize was at once discovered.

Both before and since Darwin's day the question of the absence or presence of acute smelling powers in birds has been much discussed, and the negative view has been maintained by many ornithologists of repute. To this question Mr. J. H. Gurney now makes a welcome and interesting contribution in a recent paper "On the Sense of Smell Possessed by Birds" (*Ibis*, 1922, Eleventh Series, iv, 225). After recounting the history of the discussion and making reference to the anatomical facts and experimental findings, he deals at length with the observational evidence in favour of the existence of an acute sense of smell in certain species. Among these the rook and some woodpeckers are cited on account of the accuracy with which they seem able to locate hidden grubs, below the ground in one case and beneath the tree-bark in the other. Various petrels are also mentioned, some of these being credited by good observers with the power, for instance, of detecting offal thrown overboard by fishing boats even in thick mist. Geese and ducks, too, have very frequently been thought to possess powers of smell, and in the Norfolk duck-decoys the watching decoyman customarily burns peat or the like to prevent the birds scenting him down-wind. Other birds, notably the great bustard, commonly forsake their nests if their eggs have been handled. The most striking case, however, is that of the vultures of different kinds which are familiar in many parts of the world. It is indeed difficult to explain on any other theory than that of scent how these birds of ill-omen should know when a death has occurred in a house, congregating on the roof as if in the hope of gaining access to the corpse which they cannot possibly have seen: the same faculty was traditional in this country as regards the raven, when that species was commoner than it is now. Against all this, however, there is a mass of testimony from naturalists and sportsmen that birds show little or no power of detecting the presence of an enemy, even if approaching down-wind, until either sight or hearing comes into play. The success with which bird photographers can conceal themselves close to birds' nests, for instance, is in marked contrast to the difficulty experienced in studying wild mammals. In the case of vultures, in particular, there is also the evidence of the experiments already quoted, and the experience of sportsmen in India that killed game is safe from these birds if left covered from view.

In view of the weakness of the evidence obtainable by direct observation, due to the difficulty of eliminating the possible action of the other senses under ordinary conditions, one would naturally look with hope to experimental methods. These, however, have not been altogether neglected, and the results have been disappointingly inconclusive. Bachmann's experiment, already quoted from Darwin, seems to be one of the best on record. Another essay was Dr. Alexander Hill's experiment (Nature, February 2, 1905) with domestic Turkeys, to which he offered alternative dishes of the same food, one untainted and the other containing some such substance as asafœtida, essence of anise, or oil of lavender. The results were very unsatisfactory, the birds appearing to be indifferent not only to the smell but also to the taste of the noxious substances. In America, Dr. R. M. Strong has tried the effect of placing hidden food close to doves confined in boxes which could be regulated to admit or to exclude odouis. Here again the results were negative, no notice being taken of the food by any of the birds. To these may perhaps be added the experiment carried out by Prof. Watson and Dr. Lashley on the noddy and sooty terns of the Tortugas Islands off the coast of Florida. These investigators were studying the homing faculties of breeding terns, and in some cases they tried the effect of sealing up the birds' nasal chambers with wax: here again no difference in behaviour was observable. This last experiment is of special interest because it had for its object the testing of the theory that the olfactory apparatus may function not as an organ of smell but as a mechanism for detecting the temperature or humidity of the wind and thus as an aid to directional guidance during prolonged flight.

There is, then, a well-developed olfactory apparatus in birds which one is reluctant to consider altogether ineffective, and there are instances of behaviour which are difficult to explain except on the supposition that an acute sense of smell exists in the species concerned. On the other hand, there is a greater mass of evidence of behaviour suggesting that the sense is not developed to any important extent, and the results of experiments—so far as they can be considered satisfactory at all—point in the same direction. It accordingly remains difficult to arrive at any definite judgment on the question, and scepticism as to the existence of any very efficient sense of smell in birds is probably still warranted. As Mr. Gurney says, the *onus probandi* rests with the upholders of the scenting theory.

The Hull Meeting of the British Association.

It is ninety-one years since the British Association for the Advancement of Science was founded, in Yorkshire, and it is sixty-nine years since the Association paid its single visit to Kingston-on-Hull. One prominent Hull citizen, the head of an important industry, who was present at the Hull meeting *as a member* is still living, but it is not anticipated that many others will remember the previous Hull meeting.

By the appointment of a strong executive committee and numerous sub-committees the arrangements for the Hull meeting are well in hand, and it is hoped that the attendance at Hull may exceed that at Edinburgh; everything possible is being done to attain that object.

Situated on the broad estuary of the Humber, at the junction of the river Hull, King Edward I., so long ago as 1299, saw the geographical advantages of the

town, and acquired the site from the monks of Meaux, from which date it became Kingston-on-Hull, and he gave a charter granting a fair (which is still held) and other privileges, which are yet preserved. Formerly a walled town, it played an important part in the Civil War in 1642, and still retains a number of buildings prior to that date which exhibit architectural features of interest.

To-day the city has nearly 300,000 inhabitants, many of whom obtain their livelihood from the fishing, shipping, and ship-building industries, and from the great works and mills connected with the production of oil, cattle food, flour, cement, black lead and blue, tar, paints, etc. There are also important fruit and wool markets, and many acres of timber yards. Enormous docks extending for miles accommodate shipping from all parts of the world, and in connexion with them are great warehouses and important railway and canal communications. In recent years, the King George Dock, one of the most up-to-date in the country, has been opened, a fine river-side quay has been erected, and there are elaborate appliances for the prompt handling of coal and for the storage of mineral oil. All this means that there is much of interest in the city to scientific workers.

Situated at the foot of the Yorkshire Wolds, Hull enjoys the position of being surrounded by a thinly populated area and has no other large town within many miles. It has special rail facilities for access to Scarborough, Filey, Flamborough, and other charming parts of the Yorkshire coastline, second to none in the country for variety of scenery and grandeur of cliff. Similarly the fine cathedrals and churches at York, Beverley, Selby, Patrington, Bridlington, Howden, and Hedon, well known throughout the country for their architectural charms, can easily be approached.

The plain of Holderness, with its cliffs of glacial sands and clays, provide problems for the glacial geologists, and rarely does it happen that so extensive and varied sections are available for study. The chalk wolds form a prominent feature, and quite apart from their geological and artistic attractions, were formerly thickly peopled by Briton, Roman, Saxon, and Dane, whose earthworks, burial mounds, and other remains still form attractive features in the landscape. During half a century the late J. R. Mortimer excavated most of these sites, and gathered together the contents of more than 350 burial mounds in his museum at Driffield, which has since been purchased for the Hull Corporation.

The Humber area itself has many problems of interest to the engineer, botanist, geologist, zoologist, and antiquary; while Spurn Point, with its questions of the sites of the lost towns of the Humber and of the coast, is of more than ordinary general interest.

During the Hull meeting special trains and other facilities will enable members to visit the various and numerous attractions in the East Riding and in North Lincolnshire; and already arrangements have been made for visits to be paid to places likely to interest the members.

In Hull itself, besides the fine old buildings already referred to, there is the Holy Trinity Church, one of the largest parish churches in the country, and certainly one of the oldest brick buildings still extant. In recent years the town has been entirely re-planned and largely rebuilt, fine wide thoroughfares having been cut through slum property, and these are lined with magnificent shops and public buildings. Of special interest to the visitors will be the old Trinity House and its Museum in Trinity House Lane; the birthplace of William Wilberforce, an Elizabethan mansion in High Street, now Hull's Historical Museum; the Museum of Natural History and Archæology at the Royal Institution, Albion Street; the Museum of Fisheries and Shipping at the Pickering Park; the Art Gallery in the City Hall; the Central Public Library in Albion Street, the Art School, and Technical Schools, and the old Grammar School (dated 1584) in the market place, all of which will be available to the visitors.

The city, being built on alluvium, is remarkably flat; its many miles of roads are excellently paved with wood blocks or asphalt, which, with the wide streets and fine buildings, give an appearance of cleanliness which is the envy of many larger cities. Hull is the only city in the country with its own telephones; its water supply is of the best, being drawn from chalk; and through the generosity of various benefactors and municipal enterprise, the city is well provided with public parks.

The various large engineering and manufacturing firms in Hull and district are taking keen interest in the meeting, and invitations to visit their works have been received. The Yorkshire Literary and Philosophical Society, at York, is issuing invitations for the members to visit its museum and grounds, and will provide afternoon tea, while the Lord Mayor of York will give a special welcome and has invited the members to visit the Guildhall and Mansion House. Hearty invitations have also been received from the Mayors of Scarborough, Bridlington, and Beverley to visit their respective towns, and each is doing his best to enable members to view the town's attractions, and refreshments will, in each case, be provided. The North Eastern Railway Company is taking exceptional pains to provide special trains, reduced railway fares, and late train facilities, in order to give the members every possible opportunity of visiting different places in East Yorkshire.

The local programme is a particularly attractive one, and the various lectures and addresses have an important bearing upon the district. For his presidential address Sir Charles Sherrington will take as his subject "Some Aspects of Animal Mechanism."

During the week the addresses of the sectional presidents will be delivered as under: "The Theory of Numbers," Prof. G. H. Hardy; "Research Problems in the Sugar Group," Principal J. C. Irvine; "The Physical Geography of the Coal Swamps," Prof. P. F. Kendall; "The Progression of Life in the Sea," Dr. E. J. Allen; "Human Geography: First Principles and Some Applications," Dr. Marion Newbigin; "Equal Pay to Men and Women for Equal Work," Prof. F. Y. Edgeworth; "Railway Problems in Australia," Prof. T. Hudson Beare; "The Study of Man," Mr. H. J. E. Peake; "The Efficiency of Man and the Factors which Influence," Prof. E. P. Cathcart; "The Transport of Organic Substances in Plants," Prof. H. H. Dixon; "The Proper Position of the Landowner in Relation

to the Agricultural Industry," Right Hon. Lord Bledisloe; "Educational and School Science," Sir Richard A. Gregory. The lamented death of Dr. W. H. R. Rivers deprives the psychology section of its president-designate. He had chosen as the subject of his address "The Herd-instinct and Human Society."

Among the subjects of joint discussions are: "Economic Periodicity," "The Origin of Magnetism," "Psychoanalysis and the School," "Mental Characters and Race," "The Present Position of Darwinism," "Vitamins," "The Possibility of increasing the Food Supply of Great Britain," and "Reformed Mathematical Teaching."

There will also be evening discourses on "The Atoms of Matter," by Dr. F. W. Aston, and "Fishing: Old Ways and New," by Prof. W. Garstang.

Special efforts are being made by the local secretaries at the Guildhall, Hull, to secure a large list of members, as by so doing it is hoped substantial grants may be made to the Association towards the advancement of science in its various ramifications. T. S.

Obituary.

Dr. W. H. R. Rivers, F.R.S.

Dr. William Hale Rivers Rivers, whose death occurred on June 4 at the age of fifty-eight years, came to Cambridge, at the invitation of Sir Michael Foster, in October 1893, to lecture on the psychology of the senses, and was made University lecturer in physiological and experimental psychology in December 1897; these two subjects were separated in 1907, when Rivers was made lecturer in the physiology of the senses. By this time he had established the Cambridge School of Experimental Psychology, which has produced many distinguished psychologists.

In 1898 Rivers joined the Cambridge Anthropological Expedition to Torres Straits and had charge of the psychological work, in which he was ably helped by his pupils, C. S. Myers and William McDougall. This was the first occasion on which trained psychologists with adequate equipment had attempted to investigate the psychology of natives in the field, and valuable results were obtained. While studying the psychology of the Torres Straits Islanders, Rivers began to collect genealogies in order to ascertain how far aptitudes or disaptitudes ran in families. He very soon found that the genealogies revealed a number of valuable data with regard to vital statistics, such as the number of births and deaths in a generation, the proportion of the sexes, the effects of fresh strains coming into a family, and the like. This method of research enabled him to record kinship terms with accuracy, and a consideration of them led to a study of social organisation. He also found that certain social duties and privileges were confined to certain specific relationships. Thus step by step he was led to realise the prime importance of social grouping for an understanding of social structure and function, and he found that the genealogical method was best fitted to supply the necessary data. On joining the Expedition, Rivers went out with the sole object of studying comparative psychology; he came back a keen ethnologist, having in the meantime forged a new instrument of research.

Four years later, in 1902, he went to south India to investigate the Todas, and in his important monograph ("The Todas," 1906) on that small but most interesting people, he proved once more the value of the genealogical method. His researches demonstrated how a trained mind, sympathetic manner, and scientific method can accomplish a great deal of first-class work in a relatively short time.

His first expedition to Melanesia was made in 1908, when he devoted most of his time to the Solomon Islanders. The practical result of his work there was the publication in 1914 of his monumental "History of Melanesian Society." The Melanesians were usually regarded as primitive folk of low culture, but Rivers demonstrated the existence of at least four layers of culture, due to as many migrations into that area. He dissected out, as it were, the main constituents of each layer, and showed that certain beliefs, rites, customs, and objects were found to be linked together in an organic whole in each layer or complex. He also discussed acutely the probable effects of one culture upon another, and showed that certain conditions which had usually been considered as due to social evolution were better regarded as a case of social adjustment between a pre-existing and an immigrant custom. The method formulated by Rivers is one of prime importance and is capable of indefinite extension to other peoples.

As an example of the continual growth of the mind of Rivers and his intellectual honesty, it is interesting to note that in his presidential address to Section H of the British Association in 1911, and in his "History of Melanesian Society" (1914), he points out the change that had taken place in his standpoint. The greater part of the book had been written as an evolutionist, and, in common with other English ethnologists, he believed that similarities of custom and belief are the results of the uniform reaction of the human mind to similar conditions. A further consideration of the facts and problems with which he was then occupied led him to the view that these similarities are the result of diffusion from a common source by means of migration—a view which certain older British ethnologists had held, though it was temporarily neglected. This change of standpoint prepared Rivers for an enthusiastic acceptance of the main principles enunciated by Prof. G. Elliot Smith in his "Migrations of Early Culture" (1915), and ever after Rivers was a keen supporter of cultural migrations.

Throughout this time Rivers continued teaching in the School of Psychology, and maintained his interest in that subject. He also made researches on the influence of alcohol and other drugs on fatigue, and on cutaneous sensibility in collaboration with Dr. Henry Head.

During the period of the war, Rivers was made temporary captain in the R.A.M.C., and naturally occupied himself with psychopathology. He was appointed Medical Officer to the Military Hospital, Maghull, later to the Craiglockhart War Hospital, and finally was psychologist at the Central Hospital R.A.F.

His wide knowledge, not only of psychology but of human nature, gained by investigation of various types of natives, his interest in the minds of all with whom he came in contact, together with a broad sympathy and charming manner, rendered him peculiarly fitted for this delicate and highly important work. His success was very great, and he kept in touch with as many of his old patients as was possible, and as their letters prove, they regarded him with intense gratitude and affection. The experience thus gained enabled him to produce his later important works, such as "Instinct and the Unconscious," and his lectures and papers on dreams. He accepted many of Freud's conclusions, but carried them to a very different issue in the light of his own observations during his military service.

From the foregoing it is evident that the mind and sympathies of Rivers were not only continually becoming more intensive, but were simultaneously broadening; he regarded all human conditions as the appropriate study of psychology and ethnology. This is illustrated by his last phase, when friends in London, knowing his interest in labour conditions, invited him to stand as Labour candidate for Parliament for the University of London. He agreed to do so, as he felt that his special knowledge might be of use under the present critical conditions; it was not political influence that attracted him, but merely a desire to give his best to his fellow-men; to quote his own words: "To one whose life has been passed in scientific research and education the prospect of entering practical politics can be no light matter. But the times are so ominous, the outlook, both for our own country and the world, so black, that, if others think that I can be of service in political life, I cannot refuse."

It seems almost superfluous to point out what a loss the death of Dr. Rivers is to psychology and ethnology. His keen critical mind and his insistence on scientific method were of inestimable importance to these young sciences; he, more than any one else, was establishing ethnology as a scientific discipline. It is impossible to indicate what his death means to his many friends.

A. C. HADDON.

DR. WILLIAM CARRUTHERS, F.R.S.

DR. WILLIAM CARRUTHERS, who died on June 2 at the age of ninety-two years, was a familiar figure in the botanical world in the latter half of the last century. He was born at Moffat, Dumfries, in 1830, and educated at Edinburgh with the view of entering the Presbyterian ministry, but decided in favour of a scientific career. In 1859 he was appointed assistant in the Department of Botany of the British Museum to J. J. Bennett, who had recently succeeded Robert Brown as Keeper of the department. In 1871 Dr. Carruthers followed Bennett in the Keepership, which he held until his retirement in 1895. His tenure of office was marked by a great development of the department. The removal of the natural history collections to the new museum in the Cromwell Road in 1881 afforded a unique opportunity for improvement and expansion; and the arrangement and equipment of the suite of galleries assigned to botany, including the great herbarium and the excellent botanical library, approached through a fine exhibition gallery, are a lasting memorial of Dr. Carruthers's knowledge and skill. The development of the Cryptogamic Herbarium, with the help of Mr. George Murray, and of the special British Herbarium, based on the collection of his chief assistant, Dr. Henry Trimen, the arrangement of the valuable collection of original botanical drawings and manuscripts, the planning of the exhibition galleries, and the initiation of a series of botanical monographs, such as Crombie's Enumeration of the British Lichens and Lister's Monograph of the Mycelozoa, may be recalled as incidents of his tenure. A fuller appreciation of these activities by another colleague, Mr. James Britten, will be found in the *Journal of Botany*, 1895.

Those who worked under Dr. Carruthers cherish pleasant recollections of the association. Always kind and sympathetic, he allowed his assistants full scope in the various sections of which they were placed in charge, and himself set an example of courtesy and helpfulness to visiting students and the casual inquirer. He had a strong sense of justice, and was prepared to uphold his views. Sundry hatchets, now happily buried, could testify to his capacity as a fighter.

Elected Fellow of the Linnean Society in 1861 (he has missed by one point the position of father of the Society), for more than forty years Dr. Carruthers took an active interest in its affairs. From 1886 to 1890 he was president, and his term of service included the centenary celebration in 1888. He took a great personal interest in Linnæus, and older fellows will remember the meticulous care with which he worked up the subject of the portraits of Linnæus for a presidential address. His doctorate, Ph.D. of Upsala University, was conferred on the occasion of the bicentenary celebration of the birth of Linnæus in 1907, at which Dr. Carruthers represented the Society. In 1871 he was elected a Fellow of the Royal Society, and in the same year was appointed consulting botanist to the Royal Agricultural Society, a position which he held until 1910. His yearly reports and other communications to this Society form a valuable contribution to the economic side of botany dealing with diseases of crops, pasture grasses, the purity and germinating capacity of seed, and the like. In this connection he established in his own house a seed-testing laboratory. Dr. Carruthers was also a Fellow of the Geological and Royal Microscopical Societies, and served as president of the latter; he was also president of the Biological Section of the British Association (1886) and of the Geologists' Association (1876).

The chief contributions made by Dr. Carruthers to pure science were in palæobotany, more especially the study of the carboniferous flora. The most productive period of these researches was in the 'sixties and 'seventies, and his monograph on the fossil Cycadean Stems of the Secondary Rocks of Britain (published in the Transactions of the Linnean Society, 1870), from which the genera Williamsonia and Bennettites date, remains a classic. Though his scientific work began almost coincidently with the appearance of the "Origin of Species," he was not attracted by the Darwinian theory, which he considered was not supported by the testimony of palæobotany. Dr. Carruthers was also

keenly interested in Puritan history and biography, for the pursuit of which study his retirement from the Museum in 1895 gave increased opportunity. His younger son, John Bennett Carruthers, who predeceased him, held important botanical posts in several parts of the Empire, Ceylon, the Federated Malay States, and Trinidad. A. B. R.

ADOLPHUS COLLENETTE.

MR. ADOLPHUS COLLENETTE, who died in Guernsey on May 7, in his eighty-first year, was an active worker in local climatology and physical geography, as well as an interesting personality, full of enthusiasm for the scientific point of view. His frequent expositions of scientific discoveries and theories in addresses, papers, and articles in the local society's transactions and the local press made him a well-known figure, and undoubtedly helped to arouse a good deal of scientific interest in an island which gives special opportunities for study. He was one of the moving spirits in what has now become the Société Guernesiaise, and his very active temperament made him one of its best-known guides in the long series of excursions which it has organised to teach its members the features of the Channel Islands. It is noteworthy that the research interest was well to the fore in this work. For many years Mr. Collenette kept detailed meteorological records in succession to those of the late Dr. Hoskins, so that the book he was writing at his death on the climate of Guernsey would have been based on observations registered continuously for nearly eighty years.

Mr. Collenette read a great deal of contemporary scientific literature and studied local details in the light of this reading. His was an attitude of courageous adventure; he made frequent suggestions criticising or modifying the theories of recognised authorities, sometimes with serious evidence to back him, always, at any rate, with the stimulation of discussion and further observation as a result of his work. Like Mr. Joseph Sinel of Jersey, he concerned himself especially with the relations of land and sea, and did a good deal towards the tracing of the raised beaches and some submerged beaches around Guernsey. One set is at maximum elevations between 23 and 30 feet, another varies between 46 and 65 feet; higher elevations range up to 75 feet. Mr. Collenette tried to identify platforms of marine denudation in connection with these beaches, and claimed to show that there were former sea-levels at practically all elevations from ordnance datum up to 300 ft.

While both Mr. Sinel and Mr. Collenette broadly accepted Mr. Clement Reid's view that the coast-level has been relatively stable during the past 2000 years, they nevertheless think that, in detail, there has been slow submergence around the Channel Islands within that period, and the evidence is by no means negligible. It was characteristic of Mr. Collenette that he upheld the view that Guernsey once had an ice-cap, and he claimed to show that Guernsey is rich in primitive implements, rostro-carinates and the like, including many made of crystalline rock. On this last point judgment must be left to the future.

Mr. Collenette gave attention to problems of local fruit-growing and contributed to research on tomato diseases. He was also honorary curator of the museum at the Guille-Allès Library and shared in its pioneer efforts for scientific education. It is greatly to be hoped that in the reconstruction which must follow his death, an effort will be made to combine all the local antiquities at the now public Lukis Museum, which is so important scientifically, and thus to permit the further development of the biological and geological collections at the older institution.

THE death on April 25 of Dr. Jenö Holzwarth, professor of radiology at the University of Budapest, is announced in the issue of the *Lancet* for May 20. Prof. Holzwarth studied at one time under Prof. Röntgen and afterwards acted as surgical radiologist in the clinic of Prof. Dollinger. During the earlier years, when insufficient protective appliances were in use, he suffered injuries which later developed into malignant disease. His chief contributions to the subject of radiology were on the therapeutic side, and his main papers are to be found in the *Orvosi Letil*, Budapest, during the years 1907–12. This publication appears to have ceased since the war.

WE much regret to record the death, on June 10, of Prof. William Gowland, F.R.S., emeritus professor of metallurgy, Royal School of Mines, in his eightieth year; also of M. Ernest Solvay, the distinguished industrial chemist and founder of the Solvay Institute of Chemistry, at the age of eighty-four years.

THE *Chemiker Zeitung* of May 27 announces the death of Prof. C. V. Zanetti, Director of the Institute of Pharmaceutical Chemistry and Toxicology in the University of Parma.

Current Topics and Events.

THE second conversazione of the Royal Society this year will be held in the rooms of the Society at Burlington House on Tuesday, June 20.

AT the annual meeting of the American Academy of Arts and Sciences, Prof. A. S. Eddington and Sir T. Clifford Allbutt were elected honorary foreign members.

THE annual conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, South Kensington, on the evening of Thursday, June 29.

THE unveiling and dedication of the War Memorial in memory of the members of the Institution of Electrical Engineers who fell in the Great War will take place at the Institution building on Wednesday, June 28, at 4.30 P.M. The memorial will be dedicated by the Rt. Rev. Bishop Ryle, Dean of Westminster, and unveiled by Air Chief Marshal Sir H. M. Trenchard, Bart.

MR. GEORGE F. BAKER, chairman of the board of directors of the First National Bank in New York, who has been a trustee of the Metropolitan Museum of Art for thirteen years, has endowed the museum with a capital sum equivalent to a quarter of a million sterling. The annual income from this, which may be estimated at 56,000 dollars, is to be at the disposal of the trustees. The expenditure of the museum in 1918 was 590,782 dollars, of which 233,000 dollars was contributed by the city of New York.

BY virtue of the Importation of Plumage (No. 2) Order, 1922, the names of certain birds (which are set out below) have been added to the schedule to the Importation of Plumage (Prohibition) Act, 1921, and their plumage can therefore be imported into the United Kingdom without special licence: The common jay; the common magpie; the common starling; the Java sparrow; the West African ring-necked parrakeet; the Chinese bustard; the Green (or Japanese) pheasant; the copper pheasant; and the golden pheasant. The Advisory Committee appointed under the Act, in recommending the addition of the names of the three last-mentioned birds to the schedule, further recommended that the matter should be referred to them again for review after the expiration of twelve months. The Board of Trade accordingly desires it to be known that the addition of these birds is provisional.

IT is announced in the *British Medical Journal* that a gift of 10,000*l*. has been made to aid cancer research by Mr. and Mrs. G. F. Todman, of Sydney, New South Wales, in memory of their daughter. At the request of the donors Sir Joseph Hood has allocated the sum as follows: 4000*l*. to the Imperial Cancer Research Fund, Queen Square, Bloomsbury; 1000*l*. each to the Middlesex Hospital, the Cancer Hospital, Fulham Road, London, the Christie Hospital, Manchester, the MacRobert Endowment, Aberdeen University, and the Cancer Hospital, Glasgow; and 500*l*. each to the Radium Institutes of London and of Manchester.

MR. F. N. PICKETT, chairman of the Management Committee of St. Paul's Hospital, 24 Endell Street, W.C.2, has placed a sum of 15,000*l*. in the hands of trustees to build, equip, and endow a new laboratory for research on various diseases which afflict mankind. The laboratory will be known as the "Pickett-Thomson Research Laboratory," and will be under the honorary direction of Dr. David Thomson, formerly research assistant to Sir Ronald Ross, who has consented to become president of the laboratory. Dr. Thomson, Mr. E. R. Davies, 10 Downing Street, and Mr. E. G. Martens, Genatosan Ltd., have been instrumental in getting a yearly income of about 1500*l*. for the upkeep of the laboratory staff, and other generous business men are now invited to help by giving the necessary money to endow a Ronald Ross research fellowship for biochemical researches on the nature of cancerous growths.

THE Association to aid Scientific Research by Women announces that at its recent annual meeting thirteen essays were submitted in competition for the thousand dollar Ellen Richards Research Prize. Of these essays six were from Great Britain, five from the United States, one from Australia, and one from a Russian working at research in New York. Since its establishment this prize has been awarded five times, three times to American competitors and twice to English competitors. While the prize for 1922 was not awarded, as in the opinion of the judges none of the essays were of the same grade as those to which the prize had been awarded previously, the judges gave such high credit to the paper submitted under the pseudonym of "Excited Atom" that the grant of 1000 dollars, together with honourable mention, was awarded to the author. This is the first time the grant has been made, and it carries with it the stipulation that "the grant shall be made only on the basis of submitted work and shall be used for the immediate continuation or completion of a definite piece of research." To these conditions the author of the paper entitled "An Investigation of the Critical Electron Energies associated with the Excitation of the Spectra of Helium, and their Significance in Relation to certain Modern Views of the Stationary States of the Helium Atom," has agreed, and therefore the sum of 1000 dollars has been sent to Miss Ann Catherine Davies, Royal Holloway College, Englefield Green, Surrey. Miss Davies holds the B.Sc. degree from the University of London, 1915, and received the M.Sc. degree from the same University in 1917.

CAPT. R. AMUNDSEN left Seattle on June 3 in his schooner *Maud* for the Arctic. Before his departure he announced a change in the plans of the expedition. His original intention was to enter the pack-ice north of Bering Strait and drift across to the Atlantic side, a journey which might occupy from two to four years. Last year the *Maud* made an attempt to begin this drift, but sustained injuries which necessitated her return to port. The *Times* announces that Capt. Amundsen now intends to attempt a flight across the polar basin from Point Barrow, the most northerly point of Alaska, *via* the North Pole, to Cape Columbia in Grant Land, where a depot of food has been placed in readiness. The distance is about 1550 nautical miles, and Capt. Amundsen hopes to accomplish it in fifteen hours. Sledging outfit and provisions will be carried in case a descent on the ice is necessary. His sole companion will be the pilot, Lieut. O. Omdal, and the machine will be a Larsen plane built entirely of metal. This aeroplane has already shown that it can remain in the air for thirty-two hours. Provided the weather is clear, this aeroplane reconnaissance should settle the possibility of the existence of unknown islands in the Arctic Ocean. Capt. Amundsen hopes to be able to rejoin the *Maud* next year, and apparently intends to continue the detailed exploration of the polar basin.

NEWS from the Mount Everest expedition published in the *Times* announces that on May 21 Messrs. Mallory, Somervell, and Norton reached an altitude of 26,800 ft. on the northern side of Mount Everest.

This climb was by way of a reconnaissance and did not entail the use of the oxygen apparatus. The height attained is some 2200 ft. below the summit of the mountain, and also about 2200 ft. above the previous record in height, 24,583 ft., which was reached some years ago on K2 by the Duke of the Abruzzi. General Bruce announces that the whole expedition reached the base camp at Rongbuk glacier, at a height of 16,600 ft., at the end of April. An advanced base was established under the peak of Changtse at an altitude of 21,000 ft. The Great Lama of Rongbuk monastery, which is one of the holiest monasteries in Tibet, received General Bruce and several other members of the expedition, and put the most searching questions as to the reasons for attempting the climb. The Lama was satisfied with the view that the attempt was largely in the nature of a pilgrimage, and he gave the expedition his blessing.

Further despatches from Gen. Bruce give details of the fortunes of the Mount Everest expedition before the date of a climb to within some 2000 feet of the summit of the mountain. The weather improved in May, but new difficulties that had to be faced were the desertion of some of the local coolies and the appearance of a mild form of influenza. Yet good progress was made. Gen. Bruce describes the reconnaissance that led to the discovery of a route leading towards the Chang La or North Col of Mount Everest, and the establishment of a camp (No. 3) at 21,000 feet on a broad moraine-covered shelf under the high cliffs of the north peak of Changtse. Col. Strutt, who led this reconnaissance, reports on the difficulties in ascending the East Rongbuk glacier and particularly the side glaciers. But Major Morshead contrived to find a feasible route, and all available hands were to carry supplies up to this advanced base while Messrs. Mallory and Somervell were prospecting the route up to the North Col which was subsequently discovered. In commenting on the weather conditions, Gen. Bruce expresses the opinion that there are normally only two months of suitable weather for climbing in the region of Everest in comparison with at least four months in the West Himalayas. Dr. Longstaff thinks this estimate optimistic, and believes that there is only one month of really suitable weather.

A FULL account of the *Quest's* Antarctic voyage is published in the *Times* in articles by Mr. F. Wild, who is in command of the Shackleton-Rowett expedition. These articles amplify earlier telegraphic despatches. The *Quest* evidently had her full share of the notoriously stormy weather of the Southern Ocean, but, with able handling, avoided any serious mishap. She is evidently of too low power to be of much use among close and heavy pack, but, on the other hand, her small size makes her very suitable for investigating uncharted islands which lie clear of the ice. The visit to Zavodovski Island, the most northerly of the South Sandwich group, did not include a landing, and the weather was too misty to allow a determination of the height. Mr. Wild reports that the island has no good anchorages and very few landing-places. Volcanic activity was noticeable. At the conclusion of the cruise across the Weddell Sea, a visit was made to Elephant Island, where several landings were effected and some geological work carried out. Geological work was also done in Cooper Bay and other bays on the northern side of South Georgia. In addition to the soundings in the Southern Ocean and Weddell Sea, several lines of soundings have been taken off the coast of South Georgia. After calls at Tristan da Cunha and Gough Island, where landings will be made if weather permits, the *Quest* will sail for Cape Town, where she should arrive this month.

THE report of the council of the Illuminating Engineering Society, presented at the Annual Meeting on May 25, contained a summary of useful work, a feature being the variety of topics dealt with during the session and the opportunities afforded for co-operation with other bodies. Thus "The Use of Light in Aerial Navigation" was discussed at a joint meeting with the Royal Aeronautical Society, "The Lighting of Public Buildings" in conjunction with the Royal Institute of British Architects, and the "Use of Light in Hospitals" in co-operation with the Royal Society of Medicine. Attention is also directed to the resumption of international relations in the scientific world, an event of special interest last year being the first technical session of the International Illumination Commission, at which many countries were represented. The presidential address delivered by Sir John Herbert Parsons also aptly illustrated the need for co-ordination of physical and physiological science. As an eminent ophthalmic surgeon, Sir John is familiar with the complexities of vision, and was able to show how important a knowledge of this subject is to the proper study of such problems as photometry and the effect of "glare"—the latter a consideration which enters into daily life in many ways, notably in the use of artificial illuminants and the effect of motor-car headlights.

IN a paper on "The Indigo Situation in India," read on March 24 before the Royal Society of Arts, Prof. H. E. Armstrong criticised strongly the decision of the Government of India to discontinue the work of the Indigo Research Chemist appointed in 1916, and expressed the fear that the action taken resulted not from the prevailing need for retrenchment, but from an inability to appreciate the issues at stake. It will be recalled that Mr. W. A. Davis was appointed to investigate the whole question of indigo production in India, and that arrangements were made for his first inquiries to be concentrated on the preparation of an indigo paste of standard strength and satisfactory fineness of division which would enable the Indian product to compete successfully with the German synthetic indigotin. In spite of special difficulties resulting from the war, a satisfactory product was prepared and Indian indigo paste now has a ready sale in this country. Since 1917 the larger question of the elucidation of the biochemical processes involved in the extraction and manufacture of

indigo from the plant has been tackled, as Prof. Armstrong showed, with marked success. The research has a practical value far beyond the indigo question, since it connotes the systematic study of the physiology of a leguminous crop, thus helping to fill a lacuna in agricultural science widely recognised as one calling for early attention in view of the great economic importance of leguminous plants. In the discussion of the paper the chairman (Sir Thomas Holland), while recognising the financial difficulties of the Indian Government, deplored the decision to stop this promising research, and suggested that the funds required from the Government for its continuance would be essentially of the nature of a loan, since the special export cess levied in 1918 for assisting research on indigo could be made to support the cost of the investigation.

A SMALL brochure on "Safety First" in X-ray work, issued by Messrs. Watson and Sons, Kingsway, shows that the recommendations of the X-Ray and Radium Protection Committee have not been in vain. The two Memoranda which have been issued by this Committee are reproduced *in extenso*, and it is evident that Messrs. Watson are doing their best to induce their clients to accept the protective measures prescribed. This is a welcome step in the right direction, for if radiological work throughout the country is to be free of risk to those engaged in it, it will be brought about only by those in charge of the installations insisting upon guarantees of safety. These guarantees can be provided at a small percentage cost of such installations, and we look confidently to the time when the National Physical Laboratory Certificate of Safety will become a *sine qua non* for practical work of this character.

SIR WILLIAM TILDEN and Prof. J. C. Philip are editing for Messrs. George Routledge and Sons, Ltd., a new series of volumes dealing with chemistry. Those for which arrangements have so far been made are :—"The Metastability of Matter," Prof. E. Cohen ; "Oxidation and Reduction in Organic Chemistry," Dr. O. L. Brady ; "Physical Aspects of Organic Chemistry," Prof. T. M. Lowry ; "Atomic and Molecular Structure in Relation to Properties," Dr. I. Langmuir ; "The Energy Factor in Chemical Change," Prof. J. R. Partington ; "Space Formulæ in Carbon Compounds," Prof. J. F. Thorpe and Dr. C. K. Ingold ; "Adsorption," Prof. J. W. M'Bain ; and "The Theory of Quantitative Analysis and its Practical Application," Prof. H. Bassett.

Our Astronomical Column.

A VERY MASSIVE STAR.—A paper by Prof. Plaskett on a spectroscopic binary of very high mass was read by Prof. Newall at the meeting of the Royal Astronomical Society on June 9. The star is of the sixth magnitude, and shows two spectra with considerable difference of brightness, but both measurable. It is difficult to imagine any explanation of the double spectrum other than duplicity of the star, as the spectral type indicates a fair amount of condensation, and the distance between the stars is of the order of half an astronomical unit. As there is no evidence of light-variation, it is presumed that eclipses do not occur ; it is therefore estimated that we see the orbit open to the extent of some 15°. The minimum values of the masses are given as about 70 times that of the sun for each component, the combined mass being about four times as great as that of any previously determined.

THE ROTATION PERIOD OF MARS.—Mars is the only planet of which the rotation period is exactly known. The periods of Jupiter and Saturn are often confidently stated to the fraction of a second, but it must be remembered that these values represent merely the rates of drifting and changeable spots in the vaporous envelopes of the two planets. We cannot perceive anything of the material features forming the real surface scenery of either Jupiter or Saturn, for they appear to be continuously veiled.

Mars, however, displays its actual surface markings to our view. We detect objects on its disc which are similar in shape and position to those which were discovered and delineated by Hooke, Cassini, and Huygens in the last half of the seventeenth century. There can be no doubt that the markings seen today are identical with those traced by the old observers about two and a half centuries ago.

The rotation period of Mars, according to the best determinations, is 24 hours 37 minutes 22·6 seconds, but there is a suspicion that this is too long, to the extent of about one-twentieth of a second.

RADIAL MOTIONS OF SPIRALS AND CLUSTERS.—C. Wirtz contributes an article on this subject to *Astronomische Nachrichten*, 5153. He quotes figures for 29 spirals of which only four show approach, and deduces a systematic recession of 840 km./sec., finding for the sun's velocity 712 km. towards R.A. 54°, N. Decl. 83° ; galactic Long. 95°, N. Lat. 23°. Omitting two doubtful figures the velocity, longitude, and latitude become 693 km., 90° and 29°, a shift of 7° from the first result. It appears that the nebulæ in lower galactic latitudes tend to approach, those in high latitudes to recede, while the brighter ones (that is, either the nearer or the more massive ones) tend to approach and the fainter ones to recede.

The radial motions of ten globular clusters indicate a systematic approach of 55 km./sec., and give a solar velocity of 348 km. towards R.A. 11°, N. Decl. 77°, galactic Long. 90°, N. Lat. 15° ; or, omitting the systematic motion of approach, the velocity, longitude, and latitude become 373 km., 79° and 19°, only 12° from the first point. The number of clusters is too small for trustworthy analysis, but there is some evidence of greater velocity in low galactic latitudes, and of increasing velocity with increasing distances (using Shapley's parallaxes). There is an interesting resemblance between the apices derived from spirals and clusters, but the great difference in velocities leaves it doubtful whether it has any significance.

The author points out that trustworthy proper motions of the above spirals would enable a good estimate of their distances to be derived ; a preliminary analysis of the few proper motions available (*Astronomische Nachrichten*, vol. 206, p. 114, 1918) gave for the solar apex R.A. 110°, N. Decl. 34°, annual motion 0·027″. This point is 52° distant from the first point found from radial motions. This discordance is not too discouraging considering the meagreness of the material, and the large discordances that are found for the apex relatively to the stars belonging to the galactic system.

Research Items.

A DOG-TOOTH BREAST ORNAMENT.—The *Australian Museum Magazine* (vol. i. No. 4) gives an account, with a photograph, of a remarkable form of breast ornament procured at Rabaul, New Britain, and now on loan at the Museum. It consists mainly of canine teeth of the island dog, the teeth having been perforated and attached to a plaited fibre string base, 22½ by 7¾ inches in size. At the angles and upper centre are pendants made of teeth and shells. As only four canine teeth occur in an individual, at least 130 dogs contributed to the ornament. When worn by the chief, it is suspended from the neck by the attached finely plaited cord. It was considered of great value, and no doubt formed an heirloom of much importance.

THE CHUCHKI NATIVES OF NORTH-EASTERN SIBERIA.—In the Journal of the Washington Academy of Sciences (vol. xii. No. 8, April, 1922), Mr. H. V. Sverdrup gives an account of the Chuchki tribe, collected on Capt. Amundsen's expedition, which left Norway in 1918 with the intention of following the coast of Siberia eastward to the vicinity of Bering Strait. At Ayon Island, about 700 miles west of Bering Strait, the Chuchkis were found in possession of herds of domesticated reindeer. The tents in which they live, summer and winter, are well adapted to their nomadic life and climatic conditions, and they are heated by a flat lamp of the Eskimo type. Reindeer supply practically all their food, the animals being caught with lassoes which the young men handle with wonderful skill. They do not count years, so nobody knows his own age, but they count thirteen full moons in the year by the twelve joints on both arms from the finger tips to the shoulders, including the head for the thirteenth month. They kill old people, not through cruelty, but as an act of mercy. His sledge, axe, knife, tobacco pipe, and teacup are buried with a dead man. They are quite contented with their mode of life, and have no desire to change their habits or leave their country. They do not care for the outer world, so long as it is willing to exchange tea and tobacco for fox skins. "Civilisation would not bring them any good, so it would be well if they might remain as primitive as they are."

HEALTH IN THE TROPICS.—A paper on climate and health in the South American tropics by Dr. F. L. Hoffman was presented before the American Meteorological Society at Toronto in December 1921, and a summary is given in the *U.S. Monthly Weather Review* of January last. The author considers that false impressions prevail as to the climate of the Amazonian basin, and much which has been written is misleading and a deterrent to the settlement of a vast region with enormous economic possibilities. The climate is warm throughout the larger portion of the year, but the warmth is limited mostly to the daytime, while the nights are often distressingly cool. The chief causes of ill-health in northern South America are apparently not tropical diseases but respiratory and rheumatic affections. Chilly nights cause ill-health and result in a high mortality. It is estimated that the night temperatures are about 30° lower than the day readings. With regard to humidity, it is stated to be generally far from such a serious detriment to health and comfort as is assumed, but when a high humidity coincides with a high temperature there is a considerable increase in infant mortality.

MOSQUITO INVESTIGATION.—Of the three species of Anopheles mosquitoes capable, under certain conditions, of communicating malaria, two, *i.e. A. maculipennis* and *A. bifurcatus*, stand convicted. The third group, *A. plumbeus*, or *A. nigripes*—a sylvan species—has been less known, although strongly suspected. Recent investigations by Blacklock and Carter of Liverpool, however, tended to establish not only the possibility of their capabilities as disease carriers, but that they were more abundant in England than had been supposed. Following up this discovery, the Mosquito Investigation Committee of the South-eastern Union of Scientific Societies has for nearly two years been engaged in inquiring into the habits, breeding places, and distribution of the species in south-east England, at the instance of the Ministry of Health. The three reports of the Committee have established that the larvæ of the species is extensively distributed in certain areas, many breeding places having been located, and that eggs, after becoming dry, hatch on re-immersion. Thus drought will not destroy them. The final report to the Ministry of Health is nearly due, the Committee has issued a Circular (No. 6) with the object of clearing up some points still in doubt. The more important are:—(1) Whether the species deposit their eggs (*a*) on water, (*b*) on floating or stationary objects, or (*c*) on the wet margins of water-holes. (2) The retention of vitality of the eggs after desiccation. (3) Information as to the possible hibernation in the egg stage. We may add that the late Mr. A. W. Bacot, whose death in Egypt last April, while engaged on typhus research for the Egyptian Government, was so tragically sudden, was the chairman of, and took great interest in, the Committee's work. The present chairman is Dr. Clarence Tierney, and the hon. secretary is the Rev. T. W. Oswald-Hicks of Lesware, Linden Road, N.15, who will be glad of replies to any of the queries.

THE SMALLEST HORNED DINOSAUR.—After skilful work extending for over a year, Mr. Norman Boss has completed and mounted for the U.S. National Museum a restored skeleton of the smallest horned dinosaur that has yet been discovered. This skeleton of *Brachyceratops montanensis* is the subject of a short description, with illustrations by Mr. C. W. Gilmore (Proc. U.S. Nat. Mus., vol. lxi.). The original remains from the Upper Cretaceous of north-western Montana, first described in 1917 (U.S. Geol. Surv. Prof. Paper 103), have been supplemented where necessary from other sources and result in the building up of an individual, admittedly immature, 5 ft. 4 in. long (the skull contributing 22 in.) or about the length of the head alone of Triceratops, as shown in the view of the two skeletons juxtaposed. The height of Brachyceratops at the hips is given as 30 in., but we cannot help thinking that like other of these American reptiles of olden days it has been mounted too upstanding. In a model representing the animal in the flesh (also here figured) an attempt has been made to depict the character of the scaly skin.

FOSSIL BIRDS FROM PORTO RICO.—The "Bird Remains from the Caves of Porto Rico" have been investigated and described by Mr. A. Wetmore (Bull. Amer. Mus. Nat. Hist., vol. xlvi.). The specimens were obtained in 1916 by Mr. H. E. Anthony in connection with a natural history survey of the island of Porto Rico, undertaken by the New York Academy of Sciences in co-operation with the Insular Government of Porto Rico. The number of species is 42, of which six were described as new at intervals during 1918 to 1920, the diagnoses being here repeated, while seven belong to extinct forms. The great mass of bones appears to have come from owl pellets; those of birds larger than a thrush or blackbird are comparatively few in number,

and may have represented the prey of man, or have been introduced by accident. They vary in age, the author considers, from 100 to more than 2000 years.

MOTOR HEADLIGHTS WITHOUT GLARE.—Some researches on motor headlights were summarised by Mr. H. S. Ryland at the recent discussion on this subject before the Optical Society (NATURE, May 27, p. 694). Mr. Ryland remarked that glare was largely a matter of comparison. Two of the chief factors, the "after image" effect and the regions of insensibility surrounding the image of a bright object, varied with the size of that object. He concluded from his experiments that for a given brightness of the beam, glare varied as the square of the apparent diameter of the course. Mr. Ryland has accordingly designed a lamp with a 2 in. aperture, all the available light (less about 4 per cent. and the ordinary reflection losses) being included in the beam, the upper limit of which is normally horizontal. Tests on the road showed that such lamps yielded adequate illumination and yet could be passed by other road users without discomfort.

EFFECT OF STRESS ON THE HEAT CONDUCTIVITY OF METALS.—The measurements of Smith in 1909 (*Physical Review*, vol. 28, p. 107) and those of Johnstone in 1916 (*Philosophical Magazine*, vol. 29, p. 195) on the effect of stretching on the conduction of heat along wires showed that for most of the commoner metals stretching increased the conduction by about 7 parts in a million for each megadyne per sq. cm. of stress up to the elastic limit. Lussana's measurements in 1918 of the effect of hydrostatic pressure on the conductivity (*Nuovo Cimento*, vol. 15, p. 130) gave increases as the pressure increased at approximately the same rate up to pressures of about 3000 megadynes per sq. cm. In the April issue of the Proceedings of the American Academy of Arts and Sciences, Dr. Bridgman gives an account of his recent measurements of the effects of pressures up to 12,000 megadynes per sq. cm. on the heat conductivities of eleven metals. He finds that pressure increases the conduction in the case of lead, tin, iron, and decreases it in the case of copper, silver, nickel, bismuth and antimony. The rates of change lie between 2 and 12 parts in a million per megadyne increase of pressure.

REGULATING RESISTANCES. — A comprehensive catalogue of regulating resistances, ranging from large banks of grid resistances to small adjustable rheostats, has been issued by Messrs. Isenthal and Co. (Denzil Works, Willesden). The method of construction of a tightly wound single layer of bare wire on an insulating cylinder with a spring sliding contact of ample dimensions moving axially over the wire, is adopted up to quite large sizes for field regulating resistances of the type in which only the regulating hand wheel is in front of the board. These are made, either with a slow motion screw gear, or actuated by wires so that one turn of the wheel covers the whole range. Dimmers for incandescent lighting with the same type of resistance are also illustrated. The large grid type resistances are made up in a variety of forms for different purposes, such as meter calibration, artificial loads, and other testing work. In many of these, control is effected by putting a varying number of sections in parallel by a circular switch of substantial construction with a moving contact segment, which passes under a series of radially disposed carbon contacts resembling dynamo brushes in holders of the box pattern.

VISCOSITY AND FLASH-POINT APPARATUS. — Messrs. Gallenkamp of 19-21 Sun Street, Finsbury Square, have sent us an illustrated pamphlet describing standard apparatus for determining the viscosity and flash point. The increasing importance of petroleum products for motor fuel, lighting, heating, and lubricating purposes, together with the fact that the industry is rapidly assuming considerable proportions in this country, renders the possession of accurately standardised testing apparatus a matter of great interest, and Messrs. Gallenkamp are to be congratulated on their foresight in putting before the laboratory staffs of the oil refiner and the oil consumer the useful compendium under notice. It is unfortunate that this country, the continent of Europe, and the United States have each developed a type of viscometer which at best is merely empirical. All suffer from the drawback of a capillary far too short which is difficult to clean, and none of the instruments give absolute readings. The tables of comparison between the three types, Redwood, Engler, and Saybolt, are only approximately correct, and the range of observations is relatively narrow. Until, however, a universal viscometer has been devised the three instruments mentioned will retain their places. The pamphlet gives instructions for using Redwood's viscometer and might very well have added concise instructions for the operations of the other two. The recently described instruments of Stammer and Michell are also described and quoted. The list includes the well-known flash-point apparatus of Abel, Abel-Pensky, and Cray, and the standard distillation tests of Engler and the British Engineering Standards Association.

A CRYSTALLOGRAPHIC INDEX.—"A List of New Crystal Forms of Minerals," by Dr. Herbert P. Whitlock, was issued in April (1922) as a separately bound brochure, from the Bulletin of the American Museum of Natural History (vol. 46, Art. II., pp. 89-278). Such a systematic compendium of new crystal "forms" (groups of faces of equivalent value with respect to the symmetry) should prove of great value. Often it is very difficult, when measuring crystals of known minerals from new localities, or crystals exhibiting specially interesting features although from known localities, to be quite sure, on discovering what are apparently new and hitherto unobserved forms, that these forms have in truth never been previously observed. Crystallographic literature is now so voluminous and complex, so scattered in so many different publications, that it is a matter of great labour to be thoroughly conscientious in seeking for previous records of the observation of these possibly new forms. Indeed, it frequently happens that such a search is not as thorough as the case requires, and in the actual compilation of this list Dr. Whitlock has found many cases where forms cited as new, and forming the sole subject of a paper supposed to be of original investigation, have proved to have been previously described—and more than once—by other authorities. The scope of the compilation includes the thirty years from 1890 to 1920. The thanks of both mineralogists and crystallographers are due to Dr. Whitlock for so useful a production, which is rendered all the more valuable by the fact that full references to all the original authorities are given. Together with the abstracts of crystallographic papers which are being published by the Mineralogical Society of London, and the lists of new minerals and new forms which from time to time are being included in the *Mineralogical Magazine*, we have now the material in compact form wherewith to set in order the whole record of crystallographic achievement, and to remove the stigma of "chaotic literature" which has been with some truth attached to the literature of this subject in the not too distant past.

Iron Ore in Europe.[1]

By Prof. J. W. GREGORY, F.R.S.

THE political redistribution of the iron ores and coal supplies of Central Europe by the late war was one of the results of most portentous import to the future of the world. A clear summary of the available evidence by a well-qualified expert who represents so impartial an authority as the Geological Survey of the United States, is a valuable addition to the literature of political geology. The evidence on which the memoir is based is of very unequal value, for any individual synopsis of the iron ore position must be based on the published records, which are of varying quality in different countries; moreover, the author remarks that the Russian and Slavonic literature is available to him only at second hand.

Despite its deficiencies, inevitable in any review of the ore supplies of a continent which is such a political patchwork as Europe, Roesler's memoir is a valuable supplement to the monograph on the iron ores of the world which was published in 1910 by the International Geological Congress. Mr. Roesler has brought the information up to date and presents it in a more compact form. Moreover, he expresses the results graphically in a series of sixteen clear and instructive maps which show the distribution of the ore fields and the known and estimated qualities of ore in each.

The outstanding feature of the present position is the overwhelming predominance of France in Europe as regards supplies of iron ore. In this respect France among the nations of the world stands second only to the United States. "France has the largest reserves. She stands so clearly above the other countries of Europe that there is no question of her holding first place." The French known, probable, and possible iron ores are estimated at a total of 4,369,600,600 metric tons, a total which amounts to 35·2 per cent of the iron ore reserves of Europe; the British Isles take the second place with 18·2 per cent., Sweden is third with 12·5 per cent., the German Republic fourth with 11·1 per cent. According to the author's classification of European countries Spain is fifth with 5 per cent., for he subdivides Russia, with a total of 8·3 per cent. into the Central, Southern, and Ural regions. The Russian iron fields are so scattered that it is a great convenience to keep them distinct, for they may be developed as separate industrial areas each supplying a different group of provinces.

The British supplies accepted by Roesler are smaller than some estimates; he admits that the iron included in these estimates is present, but he considers that some of the material is of so low a grade that it should not be regarded even as possible ore. He remarks that his own figure for possible ore, 2254 million metric tons, may be too large.

Germany has fallen to the fourth place, and the unfavourable conditions of a large proportion of its ore has led to the prediction that it cannot be worked and that the future of Germany is "only that of an agrarian state." The author dismisses this hypothesis with the remark that Germany "has shown her capacity to use her resources thoroughly enough to justify the conclusion" that the ores left her will be fully exploited.

The large volume of French ores is due to the sedimentary ores in the Jurassic field of Lorraine. The sedimentary ores of Europe range from the pre-Cambrian beds at Krivoi Rog in Southern Russia to the Pliocene ores of Kerch in the Crimea, and representative beds occur in most of the geological periods; but the most important supply comes from the Jurassic, which contains 46 per cent. of the European sedimentary ores. These ores contribute 70 per cent. of the total; the replacement ores amount to 12 per cent.; the contact deposits and magnetites, of which the genesis is doubtful, amount to 16 per cent.; in reference to these ores the author appears to have overlooked the fact that some of the large Lapland masses consist of titaniferous magnetite, and to overstate the strength of the case for the magmatic origin of the Kiruna ores.

The iron ore reserves are best known in Europe, and taking this quantity as the unit, the supply in North America would be represented by three, in South America by two, in Asia by three-quarters, and in Africa by one-sixth. In both Africa and Asia, however, the amount may be expected to be increased greatly by further exploration.

The reserves of iron ore in the world are estimated as sufficient to maintain the production of 1913 for 1000 years; but if the output of iron increases at the pre-war rate of 5 per cent. per annum, the supply would be exhausted in about 130 years; but a fall in the rate of increase appears inevitable, and consequently the ore reserves will have a longer duration.

The progress of the iron industry is of primary importance to the world and its future, and is especially difficult to forecast. Hitherto, Europe has had the advantages over the United States of cheap labour and of the proximity of ore and coal. In spite of this, the United States has gained the supremacy in the iron industry through economy in labour by mass production and through the large local market for manufactured goods which is maintained by the high wages paid. Europe has now to face conditions when labour is no longer cheap, and when the low efficiency that accompanies low wages cannot be as quickly altered. The main European iron field is now separated politically from the Westphalian coal field. The part of the Lorraine field which was French before 1914 was handicapped by lack of labour, and most of the miners were Italian; and unless adequate labour can be secured for the mines, and the Westphalian coal and the Lorraine iron can be brought together under favourable economic conditions, the development of the field will be jeopardised. The Belgian iron industry is dependent on German coal and on imported ore. Austria has no coal, and her considerable iron ores will probably be exported to feed the German furnaces. The three chief ore-exporting countries, Sweden, Spain, and Norway, will probably be but little disturbed by the new conditions, which will help the Norwegian ores, since most of them need concentration and briquetting.

The large British reserves of ore, though they have the advantage of proximity to coal, may be useless should the high price of fuel render it profitable only to melt high-grade ores which must be imported. The British iron industry will no doubt adjust itself to the new conditions, but Mr. Roesler predicts that the transition will be troublesome and painful. The outlook of the iron industry in this country is indeed dismal if costs of production can be lowered only at the expense of coal and labour. That there are opportunities for saving in other ways appears clear from the fact that whereas in the United States each blast furnace has an output of 120,000 tons per annum, in Germany it is 55,000 tons, and in England only 28,000 tons.

Mr. Roesler's work concludes with an excellent bibliography.

[1] "The Iron-Ore Resources of Europe," by Max Roesler, Dept. of the Interior, U.S. Geol. Surv. Bull. 706, 1921, pp. 152+xix. pls.+32 figs.

The Photographic Plate.

THE third Hurter and Driffield memorial lecture was delivered in the theatre of the Royal Society of Arts, before the Royal Photographic Society, on May 9, by Prof. The. Svedberg of Upsala, who took for his subject "The Interpretation of Light Sensitivity in Photography." After a short general discussion of light sensitiveness from a purely photochemical point of view, particularly with regard to Einstein's law of the photo-chemical equivalent, the lecturer distinguished between *plate*-sensitiveness, *grain*-sensitiveness, and sensitiveness of the *silver-halide material* of the grain. The first is the sensitiveness that concerns the practical photographer, but the third, together with some purely physical circumstances, determines the quality of the plate, and is that to which the emulsion maker should devote most of his attention. It has been recognised only quite recently that there is a sensitiveness of the haloid which is independent of the physical properties of the film and of the size of the grains or particles.

From a statistical point of view, and with single emulsions, that is emulsions prepared at once and unmixed with other emulsions, there is a certain relationship between sensitiveness and the size of the particle, the larger grains being more sensitive than the smaller. But though the probability for a grain to become developable is greater in the case of a large grain than in the case of a smaller one, yet taking any two individual grains one cannot tell whether, on exposure, the larger or the smaller will be the first to become developable. This is accounted for by the fact that development sets in at discrete points in the halide grain and progresses from these points until the whole of the grain is converted into metallic silver. One such starting-point is sufficient to render the grain completely developable.

These centres of action are located and counted by stopping development at a very early stage, and superposing a photograph of them on a photograph of the same particles taken in a deep red light before the exposure. A statistical study of the distribution of these centres gives the interesting result that within each size-class of halide grains they are distributed according to the laws of chance. The lecturer adds, "Whether the developable centres are pre-existent in the grains in the form of especially light-sensitive points, or whether their number and position in a grain is entirely determined by the light only—eventually by the haphazard distribution of the light quanta—we are so far not able to tell."

For various size-classes of grains in the same emulsion, the average number of centres increases with the size of the grain. This leads to the assumption that as a rule all the grains of a single (unmixed) emulsion are built up of the same silver halide material of the same light sensitiveness, the larger grains being more sensitive than the smaller ones merely because of the greater probability that a larger grain may contain one, or more than one, developable centre. The average number of centres is found to be proportional to the surface area of the grains.

By the use of X-rays, which are so little absorbed that the grain is exposed to their action through its whole mass, the available centres are found to be on the surface of the grain, so that the sensitiveness of a grain is determined entirely by its surface layer. By finding the number of centres per unit area of grain surface it is possible to find the sensitiveness of the silver halide material of an emulsion, independently of the size of its grains, and this has been done for three different emulsions, demonstrating clearly the great differences in sensitiveness to light of the haloid bromide material in different emulsions. Such estimations are likely to be of value to the emulsion maker in his endeavour to prepare emulsions of new and desirable properties.

The lecturer concluded his discourse by pointing out many questions that still remain to be answered in order to perfect our knowledge of the photographic plate and its sensitiveness to light. C. J.

Agricultural Research at Aberystwyth.

THE new agricultural buildings and the Welsh plant-breeding station of the Agricultural Department, University College of Wales, Aberystwyth, were formally opened on May 20 by the Minister of Agriculture, the Rt. Hon. Sir Arthur Griffith Boscawen, Bart.

The Welsh plant-breeding station owes its origin to the foresight of Sir Laurence Philipps, Bart., of Llanstephan House, Boughrood, Radnorshire, who generously provided an endowment of 10,000*l.* for the purpose, and who further assists the station with an annual donation of 1000*l.* to its funds for a period of ten years. In 1920 the station was recognised by the Ministry of Agriculture as a research institution entitled to grants-in-aid from the Development Fund, and by virtue of a capital grant and annual grants-in-aid in addition to Sir Laurence Philipps's generous endowment, it has been possible to equip the station in a thorough and up-to-date manner.

The work in connection with the new agricultural buildings and the plant-breeding station was started in 1919. The buildings are now completed and consist of commodious and well-equipped laboratories for research in agricultural botany and agricultural chemistry, as well as lecture rooms, and a library. The laboratories of the plant-breeding station are also arranged for in the buildings and have been specially equipped in a manner suitable for the researches which are in progress. The buildings occupy the site of the old foundry near the station—practically all the laboratories and lecture rooms being, in fact, part of the original building—the alterations having been skilfully made by Mr. Bassett. In addition to the self-contained building which is now solely occupied by the Agricultural Department, Nantcellan Farm, Clarach, has been acquired for the use of the teaching department, and Frongoch Farm for the Welsh plant-breeding station. The former is situated in the Clarach Valley about three miles from Aberystwyth. It comprises about 142 acres of pasture and arable land together with about 28 acres of woodland. The main object of the farm is to furnish facilities for giving demonstrations to students and for carrying on experiments and research. It is considered eminently suitable for the purpose for which it was obtained. The latter is a farm of 92 acres and is used entirely for experimental purposes in connection with the Welsh plant-breeding station. In addition, the plant-breeding station has about 5 acres of garden ground situated a few minutes' walk from the laboratories. At the gardens the equipment consists of a large span greenhouse and an up-to-date pot culture station, together with cages and other essentials.

The formal opening marked a great advance in the facilities afforded in Central Wales for both the student and for research in the problems influencing productivity in the Principality. The investigations

conducted at the Welsh plant-breeding station are primarily intended to be of service to agriculturists in Wales, and are therefore bound to be of equal value to farmers generally in elevated areas in regions of high rainfall.

The chief aim of the station is to investigate problems connected with herbage plants with the view of producing improved strains of such important plants as red clover, lucerne, the rye grasses, cocksfoot, and all other grasses suitable for inclusion in mixtures for temporary and long-duration pastures. Researches on these lines are now well advanced, interesting reports having been issued from the station on the work so far conducted. The oat crop is also receiving detailed attention; the possibility of extending the practice of growing winter oats is being explored, and endeavour is being made to produce hardier, earlier, and stiffer-strawed varieties suitable to Welsh conditions. It should be stated that the potato, barley, and root crops are not being studied at the station.

Welsh agriculturists must not expect to see the full benefits from Sir Laurence Philipps's foresight and the developments that have followed from the foundation of the station until after the lapse of a number of years—for plant-breeding is a slow and laborious business based on the gradual building up of strains each of which can only be the outcome of prolonged investigation.

The Royal Observatory, Greenwich.

THE report of the Astronomer Royal presented at the annual visitation of the Royal Observatory, Greenwich, on June 3, deals with the year ended on May 10. The observations for the seven-year star catalogue, 1915–1921, have been concluded, practically all the stars having been observed at least seven times; they include all stars in the Backlund-Hough list north of declination −28°. The determination of their proper motions is now in progress. The working catalogue in use since January last includes all the stars brighter than the eighth magnitude (with some fainter ones in sparse regions) between North Decl. 32° and 64°. It will be remembered that the zones from N. 24° to N. 32° and from N. 64° to N. 90° were covered in recent Greenwich catalogues. The epoch 1925 is adopted for all catalogues about the present time, in accordance with a resolution of the Astronomical Union.

A change has been made in the method of determining azimuth error of the transit-circle. Formerly it depended upon observations of the nine standard polars within 3½° of the pole; a list has now been made of 70 stars the polar distances of which lie between 13° and 45°, most of them bright enough to be observed in daylight; as many of these as practicable are observed daily at both culminations, using the travelling-wire micrometer, thus greatly reducing the personality that was present in the previous method of hand-tapping used for the close polars. The latter stars will still be observed for place; their positions will no longer depend solely on double transits of Polaris, which were only obtainable for restricted periods of the year. The clock-star list has been modified by removing two very low stars and inserting eleven new ones to fill gaps.

The moon was observed on 126 nights; the average correction required to the Nautical Almanac value of the longitude is 13·38″. After the end of 1922 Brown's tables will be used in the Almanac, and there will be a discontinuity in the errors.

Eighteen consecutive divisions of the transit circle, covering an arc of 1½°, have been obliterated from some unknown cause in recent years; new divisions have recently been cut with a small steel scriber that was screwed to the bracket holding the pointer. The new divisions are very sharp, and the errors of graduation are very small.

The distribution of temperature in the neighbourhood of the instrument has been studied; thermometers are now read outside both the north and the south walls of the observing room; they frequently show differences of some degrees, depending apparently on the direction of the wind; it is therefore somewhat difficult to know what temperature should be employed when computing refraction.

The recently published volumes dealing with the results of the observations made with the Cookson floating telescope between 1911 and 1918, and with the observations and orbits of the double stars observed with the 28-inch refractor since 1892, have already been noticed in NATURE. The latter observations are being continued, 253 pairs having been measured during the year, of which 56 had separations less than 0·5″.

The Thompson equatorial has been used, as before, for the photographic determination of stellar parallaxes. In all, 896 plates have been measured during the year, and the parallaxes of 48 stars deduced, with a mean probable error of 0·009″; altogether 142 parallaxes have now been determined with this instrument.

The 30-inch reflector has been used for a photographic determination of the wave-lengths of maximum photographic intensity in stars of different colours. A grating of steel wire, 1·42 mm. in diameter, was used to produce diffraction images, the effective wave-length being found from the separation of images; the results, which were communicated to the Royal Astronomical Society, indicate that the graph connecting wave-length with spectral type is distinctly non-linear. An extension of this work, suggested by Prof. T. R. Merton, is now being commenced. A 7-inch prism has been borrowed from the joint permanent Eclipse Committee; this will be mounted in front of the 6-inch Franklin-Adams lens, for which an aluminium camera has been made; a coarse wire-grating will be placed in front of the prism.

The astrographic equatorial was used to complete the magnitude determination of stars in the Harvard polar sequence. The results, which are in good accord with those obtained at Mt. Wilson, were published in the Mon. Not. R.A.S. of last November. The instrument has now been taken to Christmas Island for the eclipse of next September. The latest report stated that the mounting had been set up, except part of the driving clock. It has been arranged to take photographs of the Kapteyn areas in zones 15° N., 15° S., and 30° S. in order to connect the northern and southern magnitude scales.

Sunspot activity declined considerably during the year; there were, however, some prominent groups, of which the largest two crossed the central meridian on 1921, May 14, and 1922, March 2.

The mean values of the magnetic elements for 1921 and the three previous years were as follows:

	Dec. W.	Hor. Force. (C.G.S. Units.)	Vert. Force. (C.G.S. Units.)	Dip.
1918	14° 27·8′	0·18464	0·43247	66° 52·8′
1919	18·2′	0·18454	0·43242	53·3′
1920	8·6′	0·18456	0·43192	51·8′
1921	13° 57·6′	0·18449	0·43183*	52·0*

* Denotes that these values are provisional.

The mean temperature for the year ended on April 30 was 50·9° F., or 1·4° above the average. October was 6·3° above the average, the warmest October for 80 years. The rainfall was 16·49 in., or 7·75 in. below the average.

Wireless time signals from Eiffel Tower, Nauen, Bordeaux, Lyons, and Moscow are recorded on a syphon recorder; a special series of rhythmic signals from Lyons, for longitude purposes, was observed between June 20 and July 12.

The Carnegie Trust and Scientific Research.

THE twentieth annual report (1920–21) of the Carnegie Trust for the Universities of Scotland contains several points of interest. In relation to scientific training and research there are three important matters to distinguish, namely, buildings and equipment; scholarships and fellowships; and part-time research assistants and lecturers. This last is a new feature of the research scheme and is to be commended as combining facility for research with experience in teaching.

So far there are thirteen of these combined posts in the four universities of Scotland and all in the departments of chemistry and physics. They are covered by an annual outlay of 3600*l*. Of the 14,419*l*. awarded to the four universities for research fellowships, scholarships and grants, nearly half is given to history, the remainder being fairly well distributed among the departments of physics, chemistry, natural history, and medicine. Of this sum 26 per cent. goes to St. Andrews, 16 per cent. to Glasgow, 15 per cent. to Aberdeen, and 43 per cent. to Edinburgh. Thus Edinburgh distinctly leads in research; but activity is specially noteworthy in St. Andrews, which, as regards the number of students in attendance, is much the weakest of the four.

As is natural, the conditions of tenure of scholarships and fellowships, which cannot be held with other remunerative appointments, lead to many resignations in the course of the year, so that of the sum initially awarded only a total of 8123*l*. has been expended. From the point of view of research this is to be regretted. The further development of the part-time assistantship scheme may in future supply a remedy.

Under the quinquennial distribution, the schemes of the universities and other institutes of learning include buildings, equipment, libraries, and endowments of chairs and lectureships. These require on the average 50,000*l*. per annum; and of this sum 72 per cent. is devoted to buildings. For new buildings in the Faculty of Arts and the Department of Zoology, Glasgow University has appropriated 91 per cent. of its share; and the new King's buildings for chemistry are absorbing 81 per cent. of Edinburgh's share. The ultimate influence of these developments on scientific research will no doubt be great; the more immediate effect will be a demand for increase of staff and a corresponding increased expenditure in the teaching of science.

Of the 65,000*l*. expended under what is known as Clause A, nearly 13,000*l*. is devoted directly to individual research; while of the remainder by far the greater part is being used for providing suitable laboratories, for extending libraries, for endowing chairs and lectureships, and for helping in the publication of books and memoirs, the influence of which on scientific progress cannot be over-estimated. In these respects the Carnegie Trust for the Universities of Scotland seems to be fulfilling admirably its high function in the advancement of science.

University and Educational Intelligence.

CAMBRIDGE.—Dr. Roderick, Emmanuel College, has been reappointed demonstrator in surgery, and Mr. E. A. Milne, Trinity College, has been appointed University lecturer in astrophysics. A grant of 50*l*. from the Worts Fund is to be made to Mr. J. L. Evans, St. John's College, towards the expenses of a journey to make researches on the economic conditions of south, central, and south-eastern Europe since the treaties of peace, and on the question of the protection of minorities under the various treaties in the same region.

It is proposed to confer Honorary Degrees on H.R.H. the Duke of Aosta, K.G., and on Col. Sir Gerald Lenox-Conyngham.

The Statute giving the University power to confer by diploma titles of degrees upon women students of a recognised institution has now been approved by His Majesty the King in Council. The University now has power to name the recognised institutions and to lay down the conditions under which students of these institutions may qualify for these titles. It may admit members of such institutions to instruction in the University as well as to the use of its libraries, laboratories, and museums, in such numbers and on such conditions as it may determine. It may allow past residence kept and examinations passed by students of Girton College or of Newnham College as partial or complete qualification for titles of degrees.

Thus after four years of struggle does the University yield what the supporters of women's higher education asked twenty-five years ago, and one is tempted to wonder what the next twenty-five years will bring, and how long it will be before the next step in this old controversy will be taken.

Col. Sir Gerald Lenox-Conyngham, Trinity College, has been appointed reader in geodesy, and Mr. W. Dawson, Gonville and Caius College, has been re-appointed reader in forestry. Mr. C. Fox, Christ's College, has been re-appointed principal of the Cambridge University Training College for Schoolmasters.

Sir Ernest Moir has offered to endow a prize in the Engineering Department in memory of his son, Rex Moir, Gonville and Caius College, who was killed in the war. This offer has been accepted.

EDINBURGH.—On Thursday, June 8, Prof. T. H. Morgan, professor of experimental zoology in Columbia University, New York, delivered a lecture in the Natural History Theatre of the University of Edinburgh to a large audience of the staff and students on "Old and New Ideas about Heredity." The vice-chancellor, Sir Alfred Ewing, presided. Prof. Morgan gave an account of the more recent developments of the work on inheritance in Drosophila which is being carried on in his laboratory. After showing that the facts of inheritance lead to the conclusion that the Mendelian characters are carried by the chromosomes and that the hereditary factors or genes are arranged in a linear series in each chromosome, he discussed briefly the evidence available for forming a rough estimate of the upper limits of size of the factors. At the close of the lecture the dean of the faculty of law presented Prof. Morgan to the vice-chancellor for the honorary degree of LL.D. The dean remarked that the ceremony was reminiscent of the graduation proceedings of an older time when the candidate for university honours was required to maintain against all comers a thesis upon some abstruse subject of his choice, and he thought the audience would agree that Prof. Morgan's treatment

of his subject had been such as to secure the unanimous vote that he had passed his trials *summa cum laude.* Prof. Morgan was then "capped" amid enthusiastic applause.

By the will of the late Mr. H. Musgrave, of Belfast, who died on January 2, the sum of about 50,000*l.* has been bequeathed to Queen's University, Belfast, and 2000*l.* to the Royal Academical Institution, Belfast.

The summer meeting of the Association of Science Teachers will be held at Oxford on Saturday, July 8. A business meeting will be held in the morning, and in the afternoon there will be a lecture by Mr. A. F. Walden, New College, Oxford.

It is announced in the *Chemiker Zeitung* that Dr. Fr. Quincke, director of the Rhenania, Aachen, has been appointed professor of technical chemistry at the Technische Hochschule, Hanover, in place of Prof. Ost, who has retired; and Prof. Adolf Sieverts of Greifswald has become professor of chemistry at the University of Frankfort-on-Main.

The new School of Public Health, which will be opened at Harvard University next September, is offering several fellowships of 1200 dollars each for the year 1922–23. Well-qualified students working for doctorates or wishing to do a definite piece of research will be given special consideration. Applications for these fellowships should reach the Secretary of the School of Public Health, 240 Longwood Avenue, Boston 17, Massachusetts, not later than August 1.

A far-reaching scheme for industrial training was recently adopted by the Convocation of the University of London. Put shortly, the proposal is that the University should co-operate with the City Guilds and cognate bodies in the selection of Boards dealing with their respective trades, and that these Boards should seek, among the workers themselves, shrewd men and women of intelligence, skill, and *savoir faire* to deal with apprentices, learners, and improvers, bestowing upon them a kind of parental care and watching over their health, their progress, and their interests generally; that such trainers should find a place in every workshop and in every factory, and should receive recognition at the hands of the Guilds and of the University as a reward for the fostering care extended to their pupils; that the industrial classes are well able to supply such persons, men and women, in numbers sufficient to impress their mark upon the rising generation of workers, and that such might be designated University *teachers, trainers*, or *tutors* in their special trades, receiving a diploma to that effect, while, to apt and industrious pupils, the term University *pupil, scholar*, or *student* might be accessible with a corresponding diploma or certificate. In the report of the committee which accompanies the scheme, details of the various activities of the University are given under six main headings, and the thought arises, how can the Senate bear the proposed increased burden? Convocation itself seems well fitted to bear it. Its members, collected in suitable centres, would no doubt gladly assist in so meritorious a movement if the University should see fit to delegate the working out of the proposed scheme to a strong central committee (or delegacy), giving it powers to recognise local centres and to entrust them with branch work of benefit to the community. Such a delegacy might have its headquarters at the University centre, and the Clerk of Convocation could be its mouthpiece. It should report annually (at least) to Convocation, and through Convocation to the Senate, which might give it authority to speak in the name of the University on all matters relating to the scheme.

Calendar of Industrial Pioneers.

June 17, 1881. James Starley died.—The son of a Sussex farmer, Starley, in 1846, at the age of 15, became gardener to John Penn, the marine engineer. Afterwards he was employed by a London firm of machinists, and in 1857 he brought out the "European" sewing machine; subsequently he turned his attention to bicycles at Coventry. To his perseverance and energy Coventry owes its position as the centre of the cycle-making industry. A monument was erected to him there in 1884.

June 18, 1861. Eaton Hodgkinson died.—Known for his valuable contributions to the study of the strength of materials and for his discovery of the "permanent set" and of the position of the neutral axis in beams, Hodgkinson was born near Northwich in 1789. In Manchester he received lessons from Dalton, and while assisting his mother in business began the researches which led to his co-operation with Robert Stephenson and Fairbairn on their experiments in connection with the Britannia Bridge.

June 18, 1912. Floris Osmond died.—A distinguished French metallurgist, Osmond was trained at the École Centrale des Arts et Manufactures, and among other appointments he held was that of chief chemist at Schnieder's works at Creusot. Here he began his researches into the microscopical structures of iron and steel. He left Creusot in 1884, settled in Paris, and devoted himself to research, becoming the founder of the allotropic school in metallography.

June 19, 1898. Sir James Nicholas Douglass died.—For thirty years Douglass was engineer-in-chief to Trinity House, in which post he succeeded James Walker. The Wolf lighthouse was built under his supervision during 1862–69 at a cost of 63,000*l.*; he also designed the lighthouses on the Great Basses and Little Basses, strengthened the Bishop's Rock lighthouse, and during 1878–82 constructed the new lighthouse which replaced Smeaton's tower on the Eddystone.

June 19, 1915. Benjamin Franklin Isherwood died.—Born in New York City in October 1822, Isherwood was one of the first officers in the Engineer Corps of the United States Navy. He was a pioneer in carrying out scientific trials of steam-engines, and in 1859 published his "Engineering Precedents," a valuable work dealing with the friction losses and power of steam-engines. In 1861 he was raised to the position of engineer-in-chief of the Navy, a post he held till 1869. Recognised as the greatest marine engineer America has produced, he was for many years an honorary member of the American Society of Mechanical Engineers.

June 21, 1885. Henri Tresca died.—A student of the École Polytechnique, and for a time an engineer in the public service, Tresca was principal inspector of French exhibits at the Great Exhibition of 1851. Afterwards he became a professor of the Conservatoire des Arts et Métiers and served as president of the Société des Ingénieurs Civils. His labours were of the highest importance to the industrial arts of France, and included researches on the strength of materials, the efficiency of machines, the flow of metals, and the application of motive power.

June 22, 1876. Robert Napier died.—Commencing business in Glasgow as an engineer in 1815, with a capital of 50*l.* and a staff of two apprentices, Napier became one of the leading shipbuilders on the Clyde, and ultimately employed 3000 men. Of him Rankine said: "Few, if any, did more to bring marine architecture to the degree of perfection it has reached; and by drawing students of practical engineering from all quarters his building yard became a school of instruction to the world."

E. C. S.

Societies and Academies.

LONDON.

Zoological Society, May 23.—Dr. A. Smith Woodward, vice-president, in the chair.—E. G. **Boulenger** and F. Martin **Duncan**: A cinematograph record of the life-history of the Axolotl (*Amblystoma tigrinum*).—H. N. **Hutchinson**: A model reconstruction of the marine reptile *Peloneustes philarchus*, a Pliosaur from the Oxford Clay.—Sir Sidney F. **Harmer**: On Commerson's dolphin and other species of Cephalorhynchus.—C. Forster **Cooper**: Miocene Proboscidia from Baluchistan.—R. I. **Pocock**: On the external characters of Scarturus and other jerboas compared with those of Zapus and Pedetes.

CAMBRIDGE.

Philosophical Society, May 15.—Mr. C. T. R. Wilson, vice-president, in the chair.—E. H. **Hankin**: An experimental investigation of soaring flight. If the loading (*i.e.* the weight lifted per square foot of wing area) of soaring animals is plotted against the span, a regular curve is obtained. The greater the span, the greater the loading. The flying-fish is a striking exception; the loading is more than eight times as much as it would be for a bird of similar size, and as the speed is at least equal to that of birds under similar conditions, the wings of flying-fishes are more than eight times as efficient as those of birds. A model of a fin-ray (×10) was made of wood and fixed, convex side forward, in front of the radiator of a motor. A manometer measured any pressure that might develop on the rear face of the fin-ray. When the air at the level of the fin-ray was "soarable," as shown by the behaviour of dragon-flies, a pressure of 6-10 mm. of water was obtained at the rear of the fin-ray when the motor was travelling at 30 m.p.h. Generally the pressure was greater at midday than at sunset, it was abolished by rain, and also if the fin-ray was so loosely fixed that it was thrown into vibration by the passage past it of the air. The shape of the ray was found to be of little importance—the only thing necessary being that there should be a sheltered area. Probably the whole wing of a bird might be so disposed as to give a sheltered area. Increase of the sheltered area also resulted in increase of speed. Entering into a descending current causes an increase of sheltered area, and the expected increase of speed has been observed with gulls, which indulge in true soaring flight (*i.e.* steep upward glides with the long axis of the bird inclined upward and pointed in the direction of travel) only when the bird is in a descending current of air. Inland soaring birds and dragon-flies show similar effects.—F. P. **White**: The projective generation of surfaces in space of four dimensions.—C. G. F. **James**: The analytical representation of the theory of congruences of conics.—Miss H. G. **Telling**: (*a*) The geometrical theory of the apolarity of quadric surfaces. (*b*) A set of fifteen quartic surfaces in space of four dimensions, and the application to the theory of cubic surfaces in ordinary space.—J. P. **Gabbatt**: The generalisation of the theory of the circles associated with a triangle by means of the theory of plane cubic curves.—B. M. **Wilson**: An asymptotic relation between two arithmetic sums.

PARIS.

Academy of Sciences, May 22.—M. Albin Haller in the chair.—The president announced the death of M. Laveran.—P. **Urbain** and G. **Urbain**: The extraction and purification of scandium from thorveitite of Madagascar. This mineral, which contains 42 per cent of scandium oxide, is fused with soda and the silica removed by washing. The residue, after dissolving in sulphuric acid, is treated with hydrofluoric acid, which precipitates scandium and rare earths as fluorides. The scandium is separated as acid sulphate after treating the fluorides with sulphuric acid, and further purified by conversion into the double sulphate of scandium and potassium.—J. **Costantin**: The Maltese cross shown by wood that has undergone traumatisms. An account of the methods of wounding the stems of chestnut, sycamore, and other plants for producing cross-like markings on sticks to be used as canes or umbrella sticks. A description is given of the changes produced by the wounds in the stem.—J. **Andrade**: Three classes of non-maintained vibratory movements.—S. **Sarantopoulos**: Positive increasing functions.—Th. **Varopoulos**: Some theorems of M. Borel.—R. **Nevanlinna**: The relations which exist between the order of growth of a monogenous function and the density of its zeros.—E. **Pagezy**: The best shape to give to propulsive helices.—P. **Fatou**: The movement of a planet in a resisting medium.—P. **Chofardet**: Observations of Skjellerup's comet made with the *coudé* equatorial at the Observatory of Besançon. Positions for May 19 and 20 are given. The comet was of about 12·5 magnitude, maximum size 1′, condensation uncertain.—A. **Schaumasse**: Observation of Skjellerup's comet made with the *coudé* equatorial at the Nice Observatory. Position given for May 19. The comet appeared as a diffuse nebulosity about 2′ in extent; magnitude 12, feeble condensation.—A. **Andant**: The variations of critical opalescence with the temperature and the wave-length of the incident light. Measurements were made on five liquids of high critical temperatures—ether and the acetates of methyl, ethyl, butyl, and isobutyl. The phenomena observed in the case of ether are described in detail.—E. **Bauer**: The electromagnetic field of the stationary projectories of Bohr.—A. **Frigon**: The experimental study of the energy losses in some commercial dielectrics.—E. **Berger**: The reduction of oxides by hydrogen. Previous results on the reduction of nickel oxide by the author and Sabatier and Espil have not been in agreement, and further experiments have now been carried out to study the effect on the reduction of the mode of preparation and drying of the nickel oxide. The velocity of reduction and form of the curve vary with the origin of the sample of oxide, hence the deduction of the existence of an intermediate oxide from a kink in the reduction curve is not sound.—A. **Damiens**: The "dynamic" allotropy of tellurium. Cöhen and Kröner have applied to tellurium a theory of allotropy termed "dynamic," according to which any homogeneous phase of a given body may be composed of several species of molecules in equilibrium. Experiments by the author on carefully purified tellurium, crystallised, fused, and distilled, do not confirm the views of Cohen and Kröner, and all the phenomena observed can be easily explained without the formulation of a new theory.—A. **Dauvillier**: The L series of lutecium and of ytterbium and the identification of celtium with the element of atomic number 72.—G. **Urbain**: The atomic numbers of neo-ytterbium, lutecium, and celtium. From the high-frequency spectra it is now possible to attribute without ambiguity the atomic numbers of neo-ytterbium (70), lutecium (71), and celtium (72). A translation of the paper appears on p. 781.—A. **Boutaric** and M. **Vuillaume**: The flocculation of colloidal sulphide of arsenic. The influence of the concentration of the colloid, of agitation, and of temperature. The experimental

results are shown graphically in four curves.—MM. **Clément** and **Rivière**: Attempts at the synthetic manufacture of mother-of-pearl by the production of chemical systems.—A. A. **Guntz**: Phosphorescent zinc sulphide. The crystalline structure of sulphide of zinc appears to play an important part in the phenomena of phosphorescence, as shown by the different duration of the luminosity of the two varieties and by the known fact that their pulverisation suppresses almost entirely the luminous emission.—A. **Job** and R. **Reich**: An attempt at the systematic extension of the preparation of organo-metallic compounds. Application to iron ethyl iodide. Organo-zinc compounds possess the advantage over the corresponding magnesium compounds that a large range of solvents can be used. The iron derivative, C_2H_5FeI, is made by the interaction of an ether solution of ferrous iodide with zinc ethyl iodide also in ethereal solution. The new iron compound was not isolated, but its existence in the solution was proved by its reactions with water and alcohol.—M. **Flajolet**: The perturbations of the magnetic declination at Lyons during the year 1920–1921.—A. **Petit**: The harmful action of farmyard manure.—A. **Policard** and Mlle. J. **Tritchkovitch**: The direct fixation of fats by the sebaceous glands. The fat absorptions were followed by the addition of Soudan red (Daddi) to the food. The mechanism of the sebaceous glands appears to act in two waves. In the first, the classical theory, the fat is elaborated by the cell, but side by side with this there is a direct fixation of the fat brought by the blood.—P. **Portier** and M. **Duval**: The variation of the osmotic pressure of the blood of the freshwater teleostean fishes under the influence of the increased salinity of the surrounding water. The fish is incapable of maintaining a constant osmotic pressure like a mammal or a bird, but there is a clear tendency towards regulation in the carp, in which the osmotic pressure of the blood increases with an increase in the proportion of salts in the water in which it is placed.—H. **Cardot** and H. **Laugier**: The linguo-maxillary reflex.—G. **Bidou**: An orientation compass for the foot.—C. **Vaney** and J. **Pelosse**: Relations between the blood and the coloration of the cocoon in *Bombyx mori*.—E. **Fauré-Fremiet** and Mlle. H. **Garrault**: Constitution of the egg of the trout, *Trutta fario*.—A. **Helbronner** and W. **Rudolfs**: The attack of minerals by bacteria. The oxidation of blende. Certain bacteria are capable of converting blende into zinc sulphate: in minerals containing the sulphides of both zinc and lead, the lead is not attacked and only the zinc is rendered soluble.—L. **Fournier**, C. **Levaditi**, A. **Navarro-Martin**, and A. **Schwartz**: The preventive action in syphilis of the acetyl derivative of oxyaminophenylarsinic acid (sodium salt). Proofs of the prophylactic and preventive action of this salt against syphilis are given. The experiments were made both on animals and on man.

Official Publications Received.

Madras Fisheries Department. The Common Molluscs of South India. By James Hornell. (Report No. 6 of 1921. Madras Fisheries Bulletin, Vol. 14.) Pp. 97-215. (Madras: Government Press.) 1 rupee.

Agricultural Research Institute, Pusa. Bulletin No. 125: The Weevil Fauna of South India, with special reference to Species of Economic Importance. By T. V. Ramakrishna Ayyar. Pp. 21+20 plates. (Calcutta: Government Printing Office.) 1.4 rupees.

Agricultural Research Institute, Pusa. Bulletin No. 126: Cawnpore-American Cotton, II. Further Field Trials (1918–1920), Spinning Trials and Market Organization. By B. C. Burt. Pp. 13. (Calcutta: Government Printing Office.) 4 annas.

Agricultural Research Institute, Pusa. Bulletin No. 127: The Coconut-Bleeding Disease. By S. Sundararaman. Pp. 8+6 plates. (Calcutta: Government Printing Office.) 8 annas.

Department of the Interior: Canada. Publications of the Dominion Astrophysical Observatory, Victoria, B.C. Vol. 2, No. 1: The Radial Velocities of 594 Stars. By J. S. Plaskett and others. Pp. 127. (Ottawa: Government Printing Bureau.)

Department of Agriculture and Natural Resources: Weather Bureau. Annual Report of the Weather Bureau for the Year 1918. Part 3: Meteorological Observations made at the Secondary Stations during the Calendar Year 1918. Pp. 353. (Manila: Bureau of Printing.)

Diary of Societies.

FRIDAY, JUNE 16.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 8.—A. C. Braham: The Final Support in Carbon Printing.

TUESDAY, JUNE 20.

INSTITUTION OF GAS ENGINEERS (Annual General Meeting) (at Institution of Electrical Engineers), at 10 A.M. and 3.—T. Hardie: Presidential Address.—Gas Investigation Committee: Research on Aeration in Atmospheric Burners.—Seventh Report of the Gas Investigation Committee: Carburetted Water Gas Plant with Waste-heat Boiler.—Report of Institution Gas Research Fellowship: Dr. A. C. Monkhouse and Prof. J. W. Cobb: The Liberation of Nitrogen and Sulphur from Coal and Coke as Ammonia.—Report of the Life of Gas Meters Committee.—Report of Refractory Materials Research Committee.—A. T. Green: The Thermal Conductivity of Refractories at High Temperatures.—Miss D. A. Jones: The Standardisation of the After Contraction Test.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. Gordon Holmes: The Symptoms of Cerebellar Disease and their Interpretation (Croonian Lectures) (4).

ROYAL STATISTICAL SOCIETY, at 5.15.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—E. Peake: The Norwich School of Painters.

WEDNESDAY, JUNE 21.

INSTITUTION OF GAS ENGINEERS (at Institution of Electrical Engineers), at 10 A.M. and 3.—Dr. C. Carpenter: Some Gas Burners and a Moral.—Dr. G. Weyman: Increasing the Rate of Carbonisation of Coal.—W. B. Leech: Reconstruction Work at Beckton.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 5.—W. H. Bidlake: The Continuity of English Architecture.

ROYAL METEOROLOGICAL SOCIETY, at 5.—J. E. Clark, H. B. Adames, and A. D. Margery: Report on the Phenological Observations for 1921.—L. S. Richardson, Dr. A. Wagner, and R. Dietzius: An Observational Test of the Geostropic Approximation in the Stratosphere.

ROYAL MICROSCOPICAL SOCIETY, at 8.—A. Chaston Chapman: The Use of the Microscope in the Brewing Industry.—A. B. Klugh: The Plunger-Pipette.—E. A. Spaul: The Gametogenesis of *Nepa cinerea* (Water Scorpion).—J. Strachan: The Microscope in Paper Making.

THURSDAY, JUNE 22.

INSTITUTION OF GAS ENGINEERS (at Institution of Electrical Engineers), at 10 A.M.—Prof. C. V. Boys: A Recording and Integrating Gas Calorimeter.

ROYAL SOCIETY, at 4.30.—*Probable Papers.*—G. I. Taylor: The Motion of a Sphere in a Rotating Liquid.—Prof. T. R. Merton and D. N. Harrison: Errors arising in the Measurement of Unsymmetrical Spectrum Lines.—Dr. E. F. Armstrong and Dr. T. P. Hilditch: A Study of Catalytic Actions at Solid Surfaces. Part VIII. The Action of Sodium Carbonate in promoting the Hydrogenation of Phenol. Part IX. The Action of Copper in promoting the Activity of Nickel Catalyst.—E. A. Milne: Radiative Equilibrium: The Relation between the Spectral Energy Curve of a Star and the Law of Darkening of the Disc towards the Limb, with Special Reference to the Effects of Scattering and the Solar Spectrum.—C. W. Hinshelwood: The Structure and Chemical Activity of Copper Films and the Colour Changes accompanying their Oxidation.—R. C. Ray: Heat of Crystallisation of Quartz.

MALTHUSIAN LEAGUE (at Kensington Town Hall), at 8.—Miss Cicely Hamilton, Mrs. Seaton-Tiedeman, B. Dunlop, and Rev. G. Lang: Birth Control the Workers' Charter.

FRIDAY, JUNE 23.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—J. W. Fisher: An Experiment on Molecular Gyrostatic Action.—Prof. A. O. Rankine and C. J. Smith: The Viscous Properties and Molecular Dimensions of Silicane.—W. N. Bond: The Pressure-Gradient in Liquids flowing through Cones.—Dr. E. E. Fournier d'Albe: Demonstration of a Mercury-Drop Method of producing Visual Effects by Means of Sound.

PUBLIC LECTURES.

(A number in brackets indicates the number of a lecture in a series.)

TUESDAY, JUNE 20.

KING'S COLLEGE, at 5.30.—Miss Hilda D. Oakeley: The Idea of Value in the History of Philosophy (1).

WEDNESDAY, JUNE 21.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. A. A. Hijmans van den Bergh: The Pathology of Hæmoglobin. (In English.)

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2747, Vol. 109] SATURDAY, JUNE 24, 1922 [Price One Shilling

Registered as a Newspaper at the General Post Office.]

MANCHESTER MUNICIPAL
COLLEGE OF TECHNOLOGY

APPOINTMENT OF AN ASSISTANT LECTURER IN ELECTRICAL ENGINEERING

The Governing Body invites applications for an Assistant Lectureship in Electrical Engineering in the College of Technology. Applicants should possess special qualifications in the subject of Wireless Telegraphy.

Salary: £300 per annum.

Conditions of appointment and form of application may be obtained from the Registrar, College of Technology, Manchester. The last date for the receipt of applications is Tuesday, 4th July 1922.

Canvassing, either directly or indirectly, will disqualify a candidate for appointment.

BIRKBECK COLLEGE.
(UNIVERSITY OF LONDON.)

The Governors invite APPLICATIONS for the post of PART-TIME LECTURER in MATHEMATICS in the Matriculation Department. Salary, £180 per annum.

Application must be made on the official form, which, together with further particulars of the post, will be forwarded on receipt of an addressed envelope.

The latest date for receiving applications is Monday, July 3.

G. F. TROUP HORNE, Secretary.

Birkbeck College, E.C.4.

LEICESTER CITY TECHNICAL SCHOOL.

Principal: J. H. HAWTHORN, M.A.

WANTED, on September 1 next, a full-time INSTRUCTOR in PHYSICS.

Salary according to "Burnham" Scale, subject to such carry-over arrangements as apply to existing staff.

Applications, accompanied by not more than three testimonials, should be addressed without delay to the REGISTRAR at the School.

F. P. ARMITAGE, Director of Education.

UNIVERSITY COLLEGE, NOTTINGHAM.

DEPARTMENT OF GEOLOGY AND GEOGRAPHY.

The Council invite applications for the position of LECTURER in GEOGRAPHY.

Applicants must have a University Degree with Honours, or some equivalent qualifications.

Salary, £300 per annum.

Further particulars and forms of application, which must be returned not later than July 1, may be obtained from the REGISTRAR.

THE UNIVERSITY OF LEEDS.

DEPARTMENT OF AGRICULTURE.

Applications are invited for the appointment of ASSISTANT LECTURER in AGRICULTURAL CHEMISTRY. Salary, £300 per annum. Further particulars may be obtained from THE REGISTRAR, The University, Leeds, who will receive applications for the appointment up to July 8, 1922.

THE UNIVERSITY OF LEEDS.

DEPARTMENT OF AGRICULTURE.

Applications are invited for the appointment of DEMONSTRATOR in AGRICULTURAL BOTANY. Salary, £250 per annum. Further particulars may be obtained from THE REGISTRAR, The University, Leeds, who will receive applications for the appointment up to July 8, 1922.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE.
(UNIVERSITY OF LONDON.)

WANTED in September, an ASSISTANT in the DEPARTMENT of GEOGRAPHY. Candidates must be under 30 years of age. Honours Degree in Geography or Geology essential. Commencing salary, £250. Apply before July 10, to SECRETARY, School of Economics, Houghton Street, Aldwych, W.C.2, giving two references.

WANTED.—Oil-Testing Apparatus, Bomb Calorimeter, and general chemical apparatus. Particulars and prices to CHEMIST, 13 St. Clement's Road, Chorlton-cum-Hardy, Manchester.

THYMO-PLAS

A new and unique method for the collection and preservation of Insects. Small cells of Plasticine, impregnated with a preservative, and celluloid covers, form an ideal means of viewing specimens without deterioration or damage.

Complete Outfits, 3s. 4d. and 6s. 6d.

Full particulars by Dr. Alfred Moore, M.D., F.E.S., 2d. Stamp.

HARBUTT'S PLASTICINE, Ltd.
49 BATHAMPTON, BATH.

SPECIAL TO STUDENTS

and those requiring a first-class microscope. We are able to offer a few only of the well-known Koristka folding travelling microscopes, which are brand new, and listed at £38, at a specially reduced price of **£20.** This offer is made to ensure immediate disposal of our stock of this model, and to make room for a slightly improved pattern which is now ready for delivery from the factory.

There are only a few for disposal, and the offer can under no circumstances be repeated. We will arrange to supply on deferred payment terms if desired, **£4** cash down and twelve equal payments of **£1:9:4.** Strict approval if desired.

SPECIFICATION. Koristka 1922 model, compact folding pattern, fine and coarse adjustment, square stage, three eyepieces, and three objectives, $\frac{2}{3}$", $\frac{1}{6}$", and $\frac{1}{12}$" oil immersion, Abbe condenser, with iris, complete in case and special platform for use of microscope on tripod stand. These are brand new 1922 instruments, not second-hand. To secure one of the limited number immediate application must be made.

THE CITY SALE & EXCHANGE,
81 ALDERSGATE STREET, LONDON, E.C.1.

BEE RESEARCH INSTITUTE.
ROTHAMSTED EXPERIMENTAL STATION.

The Committee of the above Institute will shortly appoint a BIOLOGIST as ASSISTANT attached to the ENTOMOLOGICAL DEPARTMENT to carry out research work on Apiculture. Previous experience with bees is not essential, but the successful candidate will be required to undergo the necessary training during the first year of his appointment. Apply before July 6, stating University qualifications, to the SECRETARY, Rothamsted Experimental Station, Harpenden, Herts.

ACCURATE CHEMICAL THERMOMETERS.— 110° C., 150° C., 250° F., 300° F., 2s. 6d., each; 200° C., 2s. 9d. each; 360° C., 400° F., 3s. each; 500° C., special glass, 10s. each. Also singles and sets in all graduations to 1/10°.—CHEBLD, Chesham.

WANTED.—Leitz Petrological Microscope, analyser in lower part tube. triple nose and eye pieces, convenient condenser. Reply, Box 101, c/o DAWSONS, 17 Craven St., London, W.C.2.

THE GENERAL DISCUSSIONS OF THE FARADAY SOCIETY.

The SECRETARY will send on application the latest list of available REPRINTS.—10 Essex Street, London, W.C.2.

ADVERTISER, forming Library, wishes to purchase second-hand books on Botany, Biology, Mycology, Chemistry, Physics, Agriculture, Technology, and General Science.

State edition and lowest prices to MYCOLOGIST, Mundakayam, Travancore, India.

A WELL-KNOWN FIRM OF SCIEN-TIFIC INSTRUMENT MAKERS require the services of a man experienced in the final adjusting and testing. Preference will be given to one who has some knowledge of computing. State experience, age, salary required, by letter only, to "EXPERT," c/o GIBBS SMITH & Co., 10 High Holborn, W.C.1.

ORGANIC CHEMIST, well qualified, and with 8 years' experience of research, manufacture, and analysis, requires appointment; temporary considered. Box 261, c/o NATURE Office.

SATURDAY, JUNE 24, 1922.

CONTENTS.

Editorial and Publishing Offices:
MACMILLAN & CO., LTD.,
ST. MARTIN'S STREET, LONDON, W.C.2.

Advertisements and business letters should be addressed to the Publishers.
Editorial communications to the Editor.

Telegraphic Address: PHUSIS, LONDON.
Telephone Number: GERRARD 8830.

The Influence of Science.

THE great advances of science in recent times, and the countless applications of its discoveries, have led many people to regard it as concerned only with purely materialistic things, and to forget its moral and intellectual influence. In their view science is associated with the transformation of beautiful countrysides into the slums of industrial centres, with high-explosive shells and clouds of poison gas to supersede the slings and arrows of earlier days. Nothing could be further from the truth, however, than to suppose that these debasing aspects of modern civilisation are necessary consequences of scientific progress. They are due to human greed and the same spirit of jealousy as that which led Cain to rise up and slay his brother. They are consequences of the fact that civilised man is little removed from a savage when his primitive instincts are concerned; and if he can acquire the strength of a giant from science he is prepared to use the power for his own purposes.

Science as such has nothing to do with the conquests of nations or peoples, or the upholding of dynasties, or industrial exploration. The end of all scientific investigation is the discovery of truth in the realm of animate and inanimate Nature, including man, his instincts and impulses and his social organisation. As expressed in the motto of the Royal Society, science is not bound by the words of any master, and it therefore holds itself free to examine critically any principle or doctrine in which natural facts or phenomena are involved. It represents knowledge as opposed to ignorance, light as against darkness, the beauty of truth and the truth of beauty. It seeks justification not through faith but by works, and its allegiance is to truth alone so far as human intelligence can comprehend it at any epoch. To this spirit is due not only advances by which forces of Nature are used and controlled for the benefit of man, but also intellectual expansion and the elevation of the moral sense through the understanding of the significance of natural law in determining natural events.

The influence of science upon material progress and human comfort is understood much more commonly than that of its effect upon the human mind. It is difficult for people of these times to realise the liberation of life and intellect brought about by the works of Copernicus, Galileo, Vesalius, and other pioneers of scientific learning. The very foundations of belief were shaken when the earth was removed from the position in which presumptuous man had placed it, and shown to be a minor member of a group of planets revolving round a sun which was itself only one of innumerable similar orbs in stellar space. For

holding this view, and also for describing spots observed by him on the sun, Galileo was denounced to the Holy Office in 1615, and when before the Inquisition in 1633 his condemnation by the Cardinals of the Holy Roman Church contained the words: "The proposition that the sun is the centre of the world and immovable from its place is absurd, philosophically false, and formally heretical, because it is expressly contrary to Holy Scripture. The proposition that the earth is not the centre of the world, nor immovable, but that it moves, and also with a diurnal motion, is also absurd, philosophically false, and theologically considered, at least erroneous in faith." Wherefore Galileo was imprisoned, ordered for three years to recite once a week the seven penitential Psalms, and made to swear, "I abjure, curse, and detest the said errors and heresies, and generally every other error and sect contrary to the Holy Church; and I swear that I will nevermore in future say or assert anything verbally, or in writing, which may give rise to a similar suspicion of me."

As one of his biographers has said, Galileo, like Peter, surrounded by a crowd of enemies, denied his Master; yet for more than fifty years he was the knight-militant of science, a rebel against the dead hand of tradition and authority, whether of priest or philosopher, when it was used to prevent the growth of knowledge through the evidence of the senses. For more than a thousand years the mind of man had been constrained by monkish theology and Aristotelian philosophy, and all attempts at freedom of thought were rigidly suppressed. The Holy Scriptures, together with the works of early Christian fathers and some Greek philosophers, were believed to contain the truth about all things—visible or invisible—and men used them as the final court of appeal as to what was true in Nature. When Galileo discovered the four satellites of Jupiter by means of his small telescope, the philosophers of his time would not look through the instrument to see the objects for themselves, for, as Galileo remarked, "These people believe there is no truth to seek in Nature, but only in the comparison of texts." They held that the moon was perfectly spherical and absolutely smooth, and it was in vain that Galileo appealed to the evidence of observation to the contrary: the sun was supposed to be immaculate, therefore Galileo's observations of spots upon it were illusions: two unequal masses dropped from the leaning tower of Pisa reached the base together, "Yet," he says, "the Aristotelians, who with their own eyes saw the unequal weights strike the ground at the same instant, ascribed the effect to some unknown cause, and preferred the decision of their master to that of Nature herself."

The principles of self-determination and self-government have been responsible since the Armistice for many political changes, but these are as nothing compared with the social effects of the independence of scientific inquiry typified by Galileo's life and work. The right of a man to think for himself was established, and personal observation and experiment took the place of metaphysical and philosophic speculation and dogmatic assertion. The freedom of thought and action now possessed by progressive peoples are direct consequences of the work of Galileo and other scientific pioneers.

Consider the tremendous revolution involved in the substitution of permanent natural law for the conception of a world in which all events were believed to be reflections of the moods of a benign or angry God. The doctrine of daily supernatural intervention meant that men regarded themselves merely as clay in the hands of the potter and did nothing to shape their own natural destiny. They accepted disease as an act of God instead of cleansing their houses, and believed that all the qualities they possessed, as well as the actions they took, were determined by the positions of the planets and other celestial bodies. Every organ of the human body was supposed to have its counterpart in the sky; and when Vesalius by his dissections and Copernicus by his doctrine showed that there was no relationship between the human frame and the order of the universe, the ponderous superstructure of faith and pseudo-philosophy which had been built upon it fell to pieces, and a new mental world had to be reconstructed. Instead of a few thousand stars supposed to exist to influence the earth and affect the purposes of man, we now know there are millions which can never be seen without telescopic aid and millions more that are not visible with any optical means. The universe has been increased ten-thousandfold, and the puerile ideas of three centuries ago have given place to a far nobler conception of the majesty of the universe and the power of the Creator.

The intellectual expansion thus brought about, together with the sense of justice which resulted from the knowledge of the existence and permanence of law in Nature, profoundly influenced human thought and resulted in social changes which had the greatest civilising effects. This end was not attained, however, without sacrifice. The medieval lover of science was obliged to pursue his researches in secret cells and hide his discoveries from all eyes. He was for ever haunted by the maddening vision of the stake. Human nature does not encourage ideas which shatter cherished convictions; and it is usually suspicious of all new knowledge. To probe into truth or try to lift the veil and expose eternal verities was, therefore, regarded as sacrilege by guardians of traditional faith or learning. Our first parents lost Eden because they partook of

the tree of knowledge; and it was by like association with the devil that Faust secured the knowledge of renewed youth.

This view of science is not altogether unknown even in our own times. There are still heresy hunters who, with their own literal interpretation of Biblical writ, seek to extinguish the light of new knowledge. If Darwin and Huxley had lived in the time of Bruno and Galileo they would have suffered like penalties for presenting evidence of man's relationship to other primates. Leaders of the Church now accept the principles of organic evolution, just as there is now an observatory at the Vatican, and active astronomical observers among the brothers and fathers of Catholic priesthood. The truth is great and prevails in the end. Scientific inquiry never ceases and must continually be a disturbing influence. It is applied to all occurrences in which natural facts and phenomena are concerned, and believes nothing without evidence. Science does not set out to establish or depose any particular articles of faith, but to examine critically whatever comes before it in the natural world and to testify faithfully to what is seen. The knowledge thus gained may at times appear to undermine the foundations of faith, but in the course of years there is a readjustment of mental values, in which old errors are lost. From a scientific point of view, a distinction must be made between religion as an essential human instinct and outworn theological creeds or formulæ which assert that belief in unnatural occurrences is necessary for spiritual salvation. It is because of the influence of science that the Dean of St. Paul's can now say publicly, "the materialistic view of the resurrection has never been universally held; it was denied by Origen, the ablest theologian of the third century, and no intelligent man believes it now."

Examination of evidence in the critical spirit of scientific inquiry is responsible for the change of attitude towards scriptural records of natural events and phenomena represented in this remark of Dean Inge's. Only those who remember the contumely to which Huxley and Tyndall were exposed because of their extension of scientific reason to theological fields can appreciate the revolutionary change which has occurred since their day and generation. The great controversy between the evolutionists and the creationists in the second half of the nineteenth century corresponded closely with that between the Copernicans and Ptolemaists three hundred years earlier, and in each case belief had to give place eventually to ascertained knowledge. It is the duty of science to continue to fight ignorance and all that is implied by it, to be intolerant of all that is false, to make honest doubt a virtue, and condemn credulity as an intellectual crime. We may not be more superstitious than our fathers, but the vestiges of primitive man still remain in our natures ready to throw up offshoots under emotional stimulation. Much that passes under the name of spiritualism comes within this category, and when the manifestations enter the domain of matter and energy, the methods by which they must be investigated are those of physical science—critical observation, dispassionate examination of results, and crucial test of conclusions. These are the methods by which science has become synonymous with accurate knowledge, and has led the world into the way of truth. In the present epoch of social and spiritual reconstruction, the active ministry of scientific truth is again needed to help the world to adjust itself to the new conditions which knowledge has created.

Medieval Cartography.

Legendary Islands of the Atlantic: A Study in Medieval Geography. By William H. Babcock. (American Geographical Society, Research Series, No. 8.) Pp. v+196. (New York: American Geographical Society, 1922.) n.p.

THE migration of man across the ocean has differed considerably from his movement overland. On one hand, he has succeeded in taming animals by way of improving on the exertion of his own muscular effort, and in consequence he has perforce followed natural routes determined in part by a minimum of physical obstacles and a maximum or, at any rate, sufficient food supply for his animals, Moreover, through carelessness or accident he has dropped implements or weapons which give clues to the routes he followed and the sites of his settlements. On the other hand, the passage of the sea has called forth a different effort in the art of shipbuilding and seamanship, and the hungry ocean has swallowed up the remains of many a goodly ship which, through storm or adventure, passed over the trackless deep. Moreover, the wanderings of a people leave deeper marks on the historical record than the deeds of the men to whose individual prowess the opening of the sea-ways was largely due.

The author of "Legendary Islands of the Atlantic" attempts to sift legend from fact and vision from observation, in islands depicted on medieval maps of the North Atlantic, and to obtain thereby the links in the story of Atlantic exploration. Yarns of the western sea no doubt became the stock-in-trade of mariners and enabled cartographers to fill with shoals and islands the blank of the Sea of Darkness. Though more recent observations have shown that many of

the islands do not exist as charted, the author establishes his reason for regarding them as indicative of early ocean voyages.

Europe and the North Atlantic are complementary, perhaps even supplementary, in their influence on the migration of peoples westward to populate a New World with the race stocks of the Old. Both the northern and southern seas emphasising the peninsular character of Europe are themselves the nurseries of boatmen, and with their special archipelagoes have invited and facilitated, from before the dim dawn of history, the maritime adventures which in succeeding ages led men to pass beyond the limits of the mainland to the oceanic islands, ever gazing towards the setting sun and wondering on the hidden mystery of the western horizon.

The physical form and phenomena of the ocean have not changed essentially since the dawn of history. Roughly circular in shape, the northern arc from the seas of north-west Europe to the entrance of the St. Lawrence is marked out by the island stations of the Shetlands, Faroes, Iceland, Greenland, Labrador, and Newfoundland. The southern arc swinging between the western coast of Africa with the island groups of Madeira, the Canaries and Cape Verde, and the eastern trend of South America with Trinidad and the Antilles, is emphasised in the intervening regions by prevailing Trades and equatorial currents.

It is therefore not surprising that reasonably accurate knowledge is shown of the various island groups that form the thresholds of the North Atlantic from the Mediterranean and the Northern Seas respectively. But within the central region of southern weed and northern storm and fog, and towards the west, casual, and it may be involuntary, voyages might be made. Here deceptive phenomena, begotten in part by unusual scenes and in part by fear and presentiment, or by stress and hunger, caused mythical and legendary islands to appear, with perhaps Rokel Rock or the Azores as nuclei, and produced enigmas for solution by later cartographical students.

We need not stay with Babcock's treatment of Atlantis. Few will disagree with his finding that every solution of the problem must be conjectural, and many will urge the same conclusions against the other islands upon which the author bases his arguments for the discovery of America in pre-Columbian times. Legendary islands, such as Brazil and Antillia, are not always located in the same regions of the Atlantic, but, like archæological remains, lie scattered over the map. It would have been extremely valuable if the author had plotted as accurately as possible on a modern map the various sites of some of these islands.

On many maps, of which the Catalan map of 1375 is a type, Brazil is shown as an annular island with numerous islets within. This, it is contended, represents the pear-shaped Gulf of St. Lawrence with its containing islands. Reference is made to the Sylvanus map of 1511 in support of this contention.

"Nobody doubts that it [the Sylvanus map] illustrates the St. Lawrence Gulf region, though there has been much speculation as to what unknown explorer has had his discoveries commemorated here, thirteen years before the first voyage of Cartier. Why should not a like episode of discovery and imperfect record have happened at a still earlier date?" (p. 65).

Antillia and its related islands as they appear on the Beccario Map (1435), the Pareto Map (1455), and others, are considered by Babcock to be the islands hitherto regarded as the special discovery of Columbus and his companions.

"There are two names still in common use for American regions which long ante-date Columbus, and most likely commemorate achievements of earlier explorers. They are Brazil and the Antilles. The former is earlier on the maps and records; but the case for Antillia as an American pre-Columbian map item is in some respects less complex and more obvious" (p. 144). "Surely some mariner had visited Cuba and some of its neighbours before 1435";

and again:

"We may be reasonably confident that Antillia of 1435 was really, as now, the Queen of the Antilles."

There is little record but the maps, and it is extremely difficult to determine whether these cartographical approximations are intelligent anticipations or based on experience. The Laurentian portolan (1351) with its broad sweep of Guinea and the distinctly non-Ptolemaic conception of South Africa, Schöner's globe (1515) with its Atlantic-Pacific passage, may with Brazil and Antillia fall into that voluminous class of verbal and cartographical descriptions from Homer until modern times which suggest that all recorded voyages and journeys are the outcome of innumerable "feelers," the experiences of the many upon which the triumphal entry of the discoverer is made.

The contention that these fourteenth- and fifteenth-century maps record adventures and voyages in western waters reopens in a new form the question of the trans-Atlantic voyages of Columbus and of Cabot, and it is to be regretted that Babcock merely mentions in passing the researches of Vignaud, and omits altogether the contention of Biggar for the second Cabot voyage.

The study of Greenland on the maps is somewhat inadequately dealt with, and students of these early maps would have welcomed a chapter on the relations and adjustment of the names of areas carrying such titles as Norbergia, Engronelant, Labrador, Bacallaos, etc., as shown on the Pilestrina map (1503–5) and others of a slightly later date.

The author deals with many other legendary islands, such as St. Brendan, Mayda, and Buss, the last two surviving until the opening of the nineteenth century, while the chapter on Markland reviews briefly the alleged discoveries of the Norse.

The book contains an excellent selection of reproductions and is welcomed as a contribution to the study of early cartographical efforts and their value in unfolding the story of geographical discovery.

W. H. BARKER.

Pasteur's Scientific Career.

Pasteur and his Work. By L. Descour. Translated from the French by A. F. and Dr. B. H. Wedd. Pp. 256. (London: T. Fisher Unwin, Ltd., 1922.) 15*s*. net.

BY the translation of this work Drs. A. F. and B. H. Wedd have made available to the English-speaking public one of the most complete accounts of the scientific career of Pasteur. Even the lay mind will be able to follow step by step and appreciate the series of brilliant researches which gave birth to the science of microbiology, culminating in that triumph of applied science—anti-rabies inoculation. Perhaps the very detail in virtue of which this book will appeal to those actively interested in science, will act as a deterrent to the general reading public. The first two chapters in particular, dealing with Pasteur's work on crystallography, require a degree of concentration likely to scare away all but the more determined. However, in a footnote we are told that these two chapters may be omitted without detracting in any way from the value of what is to follow. This is in fact correct, for these researches, although of great interest and of fundamental importance, serve mainly to show us that Pasteur, despite his unpromising years at school and the lycée, was possessed of a scientific mind which even at this early age bore the stamp of genius. They do not form a consecutive part of the brilliant investigations which follow and they can well be passed over.

The landmarks in the scientific career of this great man are familiar to most, and it would be out of place here to deal with them in any detail. Suffice it to say that in the first ten chapters or so we are given an account of his researches on fermentation, the question of spontaneous generation, putrefaction, aerobiosis and anaerobiosis. Here also an account is given of his study of diseases of wine and beer. Although perhaps less dazzling than his subsequent researches in the realms of animal pathology, this early work of Pasteur is the more interesting in virtue of its fundamental value. These are the foundations on which has been erected the edifice of microbiology. Without the knowledge gained by this work he would not have been able successfully to attack those future problems the solution of which obtained for him undying fame.

The remaining two-thirds of the book are concerned chiefly with his investigation of disease; diseases of silkworms, anthrax, furunculosis and puerperal septicæmia, chicken cholera, swine erysipelas, and finally rabies. Every one of these chapters is enthralling, but perhaps it is the study of chicken cholera which is of the greatest interest. Although his discoveries in this case did not lead to any practical application of great import, it was during these studies that a chance observation paved the way to protective inoculations. He had isolated the causal organism of this disease and shown that it was pathogenic for hens. Returning to his laboratory after vacation and wishing to continue his studies, he inoculated some hens with his cultures. To his surprise the birds remained perfectly well; his cultures had become avirulent. A fresh strain was isolated, and what was still more surprising, the hens which had received the avirulent culture were found now to be resistant to the new strain which control experiments showed to be virulent. Here was the starting-point of his work on virus vaccine and protective inoculation.

It is perhaps unavoidable that in a book of this nature one reads little of the man himself. However, one does catch a glimpse here and there. A man of great single-mindedness and power of concentration, he had a love of honesty which served him well throughout his work. His mind was of the well-ordered, clear, logical type which has characterised French science. These qualities bred in him a positive contempt for anything slipshod or ill-reasoned in experimental work, and when occasion called for criticism of work of this nature, Pasteur did so with a force and vehemence which showed little consideration for personal feelings. It was, however, nothing mean or little in his make-up which led him to do this, but merely anger at what he considered unpardonable blunders. He was not of those who suffer fools gladly. One is given an insight also into Pasteur's attitude to religion. Despite his success in the probing of nature's secrets, he retained unshaken to the end the faith given him by his parents. The following words taken from his speech on the occasion of his reception at the Académie Française reveal this side of Pasteur's character: "The greatness of human action is measured by the motives which inspire them. Happy are those who carry with them a God, an ideal of beauty which they obey: the ideal of art, the ideal of science, the ideal of country, the Gospel idea of virtue. Those are the living sources of

great thoughts and great actions. All are lit by the reflections of the infinite."

The translators are to be congratulated. Their task was by no means easy, but they have accomplished it in an eminently successful manner.

History of Organic Chemistry.

Geschichte der organischen Chemie. Von Carl Graebe. Erster Band. Pp. x+406. (Berlin: Julius Springer, 1920.) England, 84 m.; Germany, 28 m.

THE history of a science has often been compared to the erection stone by stone of some great edifice; but it appears to the writer that the metaphor is ill chosen inasmuch as the complete building is already planned when the foundation is laid. A closer analogy is that of a jig-saw puzzle in which the separate, irregular bits are slowly fitted into their several places whilst the ultimate result remains hidden until the whole is complete.

This is certainly true of organic chemistry, and although the general plan seems to be taking shape in a marvellous fashion, who would declare the puzzle to be near completion or attempt to forecast its final development? Looking now at the ordered arrangement of its several parts it is difficult for some of us to realise the difficulties of the early investigators, who had to make a selection from an ever-increasing mass of disconnected observations and laboriously to piece them together. It is perhaps one of the remarkable facts in the history of organic chemistry that from the publication in 1832 of the classical research of Liebig and Wöhler on "the radical of benzoic acid," which Berzelius greeted as proclaiming the dawn of a new day, few revolutionary changes in fundamental principles have occurred to retard the steady growth of the science. Even the electrochemical theory, which engaged Berzelius and his opponents of the French and German laboratories in a somewhat embittered controversy, only served to stimulate research and add new facts to the science.

It is interesting to trace the many new theories which owe their inception to the study of organic chemistry. The theory of valency was developed by Frankland in studying the organo-metallic compounds; that of catalysis was formulated by Berzelius in explanation of the ether process. Isomerism was conceived by Faraday in examining the compressed hydrocarbon gases of the Portable Gas Co. The relation of vapour density to molecular weight elucidated by Gerhardt and Cannizzaro, the theory of atomic linking advanced by Kekulé and Couper; of stereoisomerism by Pasteur, van't Hoff and Le Bel, and in recent years of dynamic isomerism, enzyme action, steric hindrance and many other phenomena, which have helped to throw new light on molecular mechanics and structure, all originated with this branch of the science.

In the volume before us, which is printed in clear type, Prof. Graebe describes in considerable detail and in simple and attractive language the history of organic chemistry from 1770 to the 'eighties of last century, and tells us that arrangements have already been completed with Dr. Hoesch to carry the story forward in a second volume. In the arrangement the author has recorded the results not only of experimental and theoretical investigations but has attempted to show by quotations from the original sources the manner in which the new ideas were given to the world, while numerous, brief biographies of chemists are introduced as their names happen to occur.

The volume has evidently been prepared with parental thought and care which the author expresses by the word *Vorliebe*, a feeling which can well be understood in one who, during a long and active career, has himself played no insignificant part in the story he relates. We can cordially recommend the book to all chemists who are interested in the history of their science.

Early British Botanists.

Early British Botanists and Their Gardens, based on Unpublished Writings of Goodyer, Tradescant, and Others. By R. T. Gunther. Pp. viii+417. (Oxford: Printed by the University Press, 1922.) n.p.

JOHN GOODYER, until recently known only as the contributor of rare plants to Dr. Thomas Johnson, the editor of the second edition of Gerard's "Herball" in 1633, and further commemorated by Robert Brown's orchid genus Goodyera, is the central personality in this absorbing volume.

About twelve years ago Canon Vaughan, rector of Droxford, a Hampshire village famous as the retreat of Izaak Walton when he retired from London, printed an article embodying fresh information, which was followed later by a longer notice by Dr. G. C. Druce in the Report of the Botanical Exchange Club for 1916, pp. 523-550, drawn up from papers in the library of Magdalen College, Oxford. Now, thanks to the assiduity of the author of the volume under notice, he, as librarian, has had the scattered notes arranged and bound, and from them has presented a picture of the man, which is a revelation. He is shown

as an active and accurate botanist, a successful cultivator, and generous in imparting his treasures to his friends. For instance, Willem Boel, the Frieslander, gathered seeds in Andalusia for Goodyer, Coys, and Parkinson, which were distributed to friends; again, from one tuber of the Jerusalem artichoke from Franqueville he raised "a peck of rootes wherewith I stored Hampsheire" in 1617.

Upon the death of Johnson, in 1644, Goodyer was unquestionably the foremost botanist in the kingdom, and his life overlapped the first anonymous essay of John Ray, his Cambridge flora, in 1660; but he was dead six years before Ray's "Catalogus" saw the light in 1670.

In addition to his knowledge of plants Goodyer knew enough Greek to translate the two works of Theophrastus, "De plantis" and "De causis plantarum"; of the former we have now an English version by Sir Arthur Hort in the Loeb Library, but the latter has never been printed in our language. Later, he began copying out the Greek text of the "Materia medica" of Dioscorides and to interline it with an English translation.

Nearly half of Mr. Gunther's volume is devoted to "Notes on contemporary botanists, mostly from Goodyer's Books and Papers." We thus become acquainted with his relations with other botanists, several of whom are unfamiliar, while many more are only slightly known to us, and from these pages we gain much. Among these may be mentioned William Coys of Stubbers in Essex; William How, the author of the first British flora and editor of Lobel's last issued work; John Parkinson, the last of the herbalists; the Rev. Walter Stonehouse, and William Browne of Magdalen, to whom his college probably owed the bequest by Goodyer of his books and papers, the foundation of the volume now under discussion.

The limits of this notice forbid any further dwelling on the contents of a volume of the greatest value and a treasure-house to everybody who is interested in British botany.

One unimportant error may be mentioned as occurring on page 84, namely, that of Mattioli's Commentaries on the "Materia medica" of Dioscorides: seventeen editions were said to be published; the actual number was nearly seventy, for Saccardo speaks of sixty at least, and he was not acquainted with all. But we close the volume with feelings of gratitude to the author; his zeal and devotion have added greatly to our appreciation of the Hampshire and Sussex botanist, whose record does so much to redeem the time when he lived from being considered a barren period for the science of botany.

B. D. J.

Functions of Industrial Research.

Research in Industry: The Basis of Economic Progress. By A. P. M. Fleming and J. G. Pearce. (Pitman's Industrial Administration Series.) Pp. xvi+244. (London: Sir I. Pitman and Sons, Ltd., 1922.) 10*s.* 6*d.* net.

THE case for research and education as the best means of assuring progress in industry is most ably demonstrated by Messrs. Fleming and Pearce, who are well known for their association in directing the Research Department of the Metropolitan-Vickers Electrical Co. Ltd., of Manchester. The book covers a very wide field, and should be read by all who are engaged either in scientific work or in industrial administration. The social aspects of the subject are kept well in view and the great importance which the scientific study of the human factor in industry is destined to take in the resettlement of industry is duly recognised, although the work of the Industrial Fatigue Board receives less attention than it deserves.

The various types of research laboratories and methods of research organisation, including the comparatively new co-operative method illustrated in British Research Associations, are dealt with in detail. Considerable space is devoted to the planning, equipment, and staffing of works research laboratories, and the financial aspect is dealt with more fully than in any previous publication.

An interesting chapter deals with the collection and distribution of information for research and industrial purposes. The problem of making an intelligence department of a works library efficiently productive might with advantage have been elaborated further, in view of the authors' special experience. Although there is need for greater co-ordination among the many agencies for collecting and abstracting scientific information, the necessity for its distribution to and absorption by the industries is infinitely more important. The British scientific worker is, perhaps, less thorough than his fellow-workers abroad in surveying the field of previous work on the problem he is investigating, and, indeed, excessive zeal in this direction may tend to limit originality and initiative. In industry, however, numerous examples of wasted opportunity and moribund conditions could be quoted which are due largely to ignorance of similar industrial practice in other countries. The awakening of inquisitiveness as to foreign methods of manufacture might prove the starting-point for a still greater receptivity among employers, and from this the step to a conviction of the desirability of actual original research is relatively small, as American experience has abundantly shown. Europe, in fact, in competing

for world markets, has more to fear from American receptiveness to new ideas than from any other single factor.

In this country the support of the Department of Scientific and Industrial Research in the foundation of Research Associations is already more than justified by its success in bringing together all types of employer, engaged in particular industries. Contact with outside scientific workers and their more enlightened competitors will inevitably result in a greater appreciation of the advantages of science by the majority of industrial leaders.

Finally, the authors deserve credit for their just appreciation of the special requirements of scientific workers engaged in pioneer research, and particularly of the ways in which such men may be encouraged to prepare for research as a vocation and to follow it without being repressed by works routine. The necessity for supporting pure science work for its paramount object of increasing the sum of human knowledge is strongly emphasised. The book is admirably produced and includes a 16-page bibliography, which should be of service to all interested in the subject.

Our Bookshelf.

Physico-Chemical Problems relating to the Soil: a General Discussion held by the Faraday Society. (Reprinted from the Transactions of the Faraday Society, Vol. 17, Part 2, February.) Pp. iii+217-368. (London: Faraday Society, 1922.) 10*s.* 6*d.* net.

The Faraday Society is to be congratulated on the issue of this volume, reprinted from its Transactions; soil investigators in this country now have, in accessible form, a study of one important branch of work from a number of aspects. The volume contains the subject-matter of the general discussion held by the Faraday Society in 1921 on "Physico-Chemical Problems relating to the Soil." There are sixteen papers grouped in the following five sections: (1) Introduction and General Papers, (2) Soil Moisture, (3) Organic Constituents of the Soil, (4) Adsorption Phenomena, and (5) Colloidal Phenomena. The student of soils will find much of interest, not only in the papers themselves but also in the *verbatim* report of the discussion which followed.

Recent work on soils from the standpoint of physical-chemistry has followed two or three main lines, which are discussed in an introductory paper by Sir E. J. Russell. The examination of the soil solution and its relation to soils on one hand and plants on the other, has been much stimulated by the method of the freezing-point depression. American investigators have done much in this direction, and the paper by Prof. Hoagland (California) gives an interesting account of the work to date. Certain assumptions are made in applying this method to the soil solution, and the deductions which follow are discussed by B. A. Keen (Rothamsted) in the course of a paper on soil moisture. Prof. Shull (Kentucky) reviews various theories on the intake of soil solution through the osmotically active membranes of the root hairs.

The part played by colloidal material in soil naturally forms the subject of several papers. N. M. Comber (Leeds) discusses the flocculation of silt and clay on the assumption that the latter is protected by a siliceous emulsoid, and C. G. T. Morison (Oxford) reviews the theories of pan formation. Dr. Mellor (Stoke-on-Trent) deals with the plasticity of clays used in the ceramic industry. The organic matter in soil is of obvious importance in any discussion of colloidal properties. A general review is given by H. J. Page (Rothamsted), and Prof. Odén (Upsala) describes his own important investigations on humus, which have proved the existence of humic acid and shown that the hypothesis of selective adsorption is not a complete explanation of soil acidity. With regard to soil acidity itself there is one review paper by E. M. Crowther (Rothamsted), while Dr. Salisbury (London) discusses the ecological aspects.

Besides acidity, many other phenomena shown by soils have been interpreted on the basis of adsorption. E. A. Fisher (Leeds) presents an able critical review of work on absorptive processes in soils, with especial reference to inorganic substances.

Finally, there are some papers dealing with more purely physical questions. Prof. Odén gives a detailed account of his elegant method of mechanical analysis and a note on the hygroscopicity of clay, Dr. Hackett (Dublin) discusses the rate of ascent of liquids in granular media, while G. W. Robinson (Bangor) specifies certain physical properties of soil in relation to survey work.

B. A. K.

A Text-Book of Aeronautical Engineering: The Problem of Flight. By Prof. H. Chatley. Third edition, revised. Pp. xii+150. (London: C. Griffin and Co., Ltd., 1921.) 15*s.* net.

A second edition of Prof. Chatley's book appeared in 1910, and during the war, when interest in aeronautics attained great heights, this book, like many others on the subject, was bought in large numbers, thus necessitating a third edition. Not very much was known about the subject of aeronautics before the war; systematic treatises had not yet appeared, and Prof. Chatley's book achieved a deserved popularity.

Now that a third edition has been issued, claiming to be "revised," the opportunity should have been taken to make the book a more proportioned, authoritative, and modern exposition. There is scarcely room in a text-book for a detailed account of the ornithopter—not because it is *a priori* clear that one should not continue to make attempts at producing machines based on the flapping-wings principle, but because a text-book should contain what is more or less accepted: it should give a safe (not necessarily orthodox) account of the principles used in practice, with some attempt at justification.

A brief introduction on the problem of flight is followed by a useful statement of essential principles. Then comes a chapter on the propeller, treated by

rather rough-and-ready methods. Much of the chapter on the aeroplane is out of date; it is scarcely correct to say that the air-pressure results for plane surfaces can be corrected so as to apply to curved surfaces by slight charges in the constants, and in any case there are plenty of experimental data for giving a correct account of cambered wings. The chapter on the dynamics of aeroplanes is not very full, while a treatment of the parachute by means of differential equations is inserted for little reason, in a book which is not really a mathematical treatise. In addition nearly three of a total of less than 150 pages are occupied with Glaisher's analysis of the motion of the balloon—with the note that it has little practical value! After the chapter on ornithopters we get a short account of dirigibles and the bodies of aeroplanes, etc. There is also a brief account of stability.

Some of the appendices are useful, although the bibliography is disarranged. Foreign names are misspelt, *e.g.* an umlaut on the "a" in Lilienthal. The author has the ability to produce a real text-book on aeronautics, but the present volume is disappointing.

S. BRODETSKY.

Die Pendulations-Theorie. Von Prof. Dr. H. Simroth. Zweite Auflage. Pp. xvi + 598. (Berlin: Konrad Grathlein, 1914.) 13.50 marks.

FIRED by a new view of the shifting of the polar axis of the earth the speculative mind of a distinguished zoologist, Simroth, conceived the idea of a relation between earth oscillation and organic development.

The merit of this oscillation theory of organic distribution was its reduction of the rise and spread of organic forms to a single process in relation to recurring secular change. Simroth assumed that the earth forms an oscillation system of a peculiar kind, such that one maximum line of stress runs north and south through Norway, Germany, the line of elevation of the Alps, and across the western Sahara, while the other companion stress line passes through Bering Strait and the Pacific, west of the American coast. Assuming also permanence of the general configuration of the oceans and continents, Simroth then makes his grand assumption, which is that the evolution of genera has recurred along the European line of maximum oscillation (which is therefore the region of creative evolution) in response to secular changes of environment. From this area of distribution those forms that are primitive migrate eastwards or westwards to areas of less disturbance, whilst the progressive forms adapt themselves to the cold of polar uplift or the warmth of equatorial depression. In this way Simroth accounts for the occurrence of allied forms in widely separated parts of the world. Beings are what they are and where they are, as a "function" of the oscillation system.

The new edition of this work does not remove the difficulties of those who refuse to accept Simroth's hypothesis. The new matter consists merely of 33 pages appended to a reprint of the first edition and contains no references to criticisms such as those of Prof. G. C. Bourne (Proc. Zool. Soc. 1911, pp. 802-805) that refer to a fundamental objection—the secondary nature of marine organisms. If Dr. Simroth has not converted his fellow-zoologists, he is not likely to make converts in other biological fields. Granted that we have no simple alternative to his view, yet the assumptions on which it rests are not in accordance with modern geological opinion; and if that is so, biological speculation on such a weak basis is only misplaced ingenuity. The earth as a system of stresses is likely to prove a much more complex theme than the one Simroth vaguely describes, while the relation between maximum stress and biological progress requires far more critical examination than he gives to it.

F. W. G.

Swiss Travel Almanac. Edited by the Swiss Tourist Information Office. Summer Season, 1922. Pp. 112. (Olten, Switzerland: O. Walter, Ltd.; London: Swiss Federal Railways, Regent Street, 1922).

THIS book is a reminder that Switzerland is ready once more to become "the playground of Europe," and it is especially an appeal to English visitors. The numerous signed essays include one by Mr. A. Latt on "English influences on Swiss intellectual life," recalling many pleasant details of *rapprochement* in the seventeenth and eighteenth centuries. Mr. Schaederlin writes finely of the brave hardihood of alpine trees. Good and readable as the essays are, the great charm of the book lies in its illustrations. The well-known scenes of tourist gatherings are relegated to the advertisement pages at the end, and throughout this modestly styled Almanac we are given an exquisite series of photographs, printed in brown, of "trees and woodlands" in the Alps. Each of these appeals delightfully to the naturalist, who will promptly consult the calendar and the tables of exchange.

G. A. J. C.

Handbook of Commercial Information for India. By C. W. E. Cotton. Pp. viii + 383. (Calcutta: Superintendent Government Printing, India, 1919.) 1 rupee: 2*s*.

MR. COTTON'S book is a useful volume which gives in a condensed form, and well arranged for reference, notes on all the principal exports of India, including origin, district of growth, processes of preparation, and conditions of export. It does not profess to be a scientific work or in any sense a rival to larger and more complete gazetteers of Indian products. It has been compiled for traders, and with this end in view notes on ports and commercial organisations are added. Among the State departments connected with trade we find a reference to the geological survey but none to the Survey of India or to the Royal Indian Marine. Does this imply that maps and charts have no bearing on trade? It is to be hoped that the demand for this book will result in the publication of an annual edition.

Das Problem der Genesis des Actiniums. Von M. C. Neuburger. Sonderausgabe aus der *Sammlung chemischer und chemisch-technischer Vorträge.* Herausgegeben von Prof. Dr. W. Hertz. Band XXVI. Pp. iii + 64. (Stuttgart: Ferdinand Enke, 1921.) 5 marks.

THE author discusses the experimental work done on the origin and transformations of actinium, and the various hypotheses which have been put forward as to the successive changes in the actinium series. He concludes that at some stages, besides α-and β-particles, particles of mass 3 and charge 2 are emitted. There is a detailed list of references, including some so recent as the year 1921.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Continuous Radiation found in some Celestial Spectra beyond the Limit of the Balmer Series of Hydrogen.

IN the account of his observations of the eclipse of January 22, 1898, published in the Philosophical Transactions, A 197, pages 389 and 399, Mr. Evershed directed attention to a curious continuous spectrum emitted by the solar chromosphere and prominences. This spectrum begins near the limit or head of the Balmer series of hydrogen lines, and extends with gradually decreasing intensity in the direction of shorter wave-lengths. In describing the phenomenon Evershed referred to the early observation by Huggins of an absorption in the corresponding region in the spectra of Vega and other stars having especially strong hydrogen lines (stars of Class A),[1] and advanced the opinion that the spectrum, like the Balmer series which it so curiously supplements, is due to hydrogen. The grounds for this view were afterward strengthened through the discovery by Wood of a continuous spectrum occurring beyond the limit of the sodium series of dark lines, under conditions of laboratory experimentation that favoured the development of the higher members of the sodium series.[2] More recently an emission spectrum, apparently identical in character with the one observed by Evershed in the chromosphere, has been found to be characteristic of the planetary nebulæ.[3] The spectrum seems also to occur in the diffuse nebula N.G.C. 1499,[4] and has been a conspicuous feature in the radiation of the novæ. It may therefore be regarded as rather a commonplace phenomenon pertaining to the spectra of celestial objects which appear to exist under conditions of strong thermal or electrical excitation. For the purposes of this note I shall use the term *outlying spectrum* in referring to it in order to distinguish it from the general continuous spectrum of more uniform distribution which is found even in the gaseous or "bright-line" nebulæ.

The outlying spectrum, as an emission phenomenon, has not, that I am aware, been observed in the laboratory, except possibly by Dufour,[5] who found an ultra-violet continuous spectrum which, however, he associated with the *secondary* spectrum of hydrogen, and not with the Balmer series. In view of its general occurrence in a large group of extremely interesting and important celestial spectra, it would seem desirable that serious effort be directed toward its development in the laboratory, with the view of establishing the circumstances of its origin. As a preliminary step in estimating the conditions likely to prove favourable for its emission it may not be out of place to recall a theoretical explanation that has been advanced to account for it.

In a paper read two years ago before the American Philosophical Society,[6] the present writer suggested that the spectrum might be explained on the basis of the Bohr theory, as resulting from the capture of free electrons by hydrogen nuclei. Although the idea was developed from independent considerations, it cannot be regarded as an original one, since Bohr, in his first paper,[7] had suggested the reverse process to account for the sodium absorption referred to above as having been found by Wood. Inasmuch, however, as he had not applied the consideration to the explanation of an emission spectrum in that region (such as was known to exist in the spectrum of the chromosphere), it seemed appropriate at the time to direct attention to that aspect of the theory, and I venture to revert to it here, both on account of its theoretical interest, and because it may possibly prove suggestive of the conditions under which the spectrum should be sought in the laboratory.

Briefly outlined, the argument is as follows: The mechanism which Bohr sets up for the hydrogen atom is a positive nucleus surrounded by an infinite series of fixed orbits in which it is possible for an electron to revolve. A line of the Balmer series is formed when an electron "jumps" from one of the outer orbits to the second one, and the complete series of lines results from the totality of transfers or jumps from all of the outer orbits. The frequency of vibration is in each case proportional to the energy set free in the transfer from the outer to the second orbit, and the frequency at the head, or limit, therefore corresponds to the energy set free in the fall of an electron from rest at infinity. An electron with an additional velocity of its own will of course give up more energy in its capture than one starting from rest, so it will have to be manifested by a radiation of proportionately greater frequency, that is to say, of less wave-length, than that of the series limit. The exact position of the resulting line will depend upon the amount of the initial kinetic energy, and since this must, in general, vary from one electron to another, the totality of these radiations should make up a continuous spectrum beginning at the Balmer limit and extending into the ultra-violet. It is thus seen that, by this theory, the Balmer series is caused by the falling inwards of electrons forming part of the atomic system, while the outlying spectrum is due to the capture of extraneous electrons. It is scarcely necessary to point out that the reasoning applies with equal force to the Ritz and Lyman series, and to other series of like character.

Preliminary to discussing this explanation it is well to calculate the initial kinetic energy required to produce the observed spectrum. The outlying spectrum can be followed in a number of planetary nebulæ to about 3340Å. This is of course an extremely rough estimate, for the spectrum is faint, and on this side fades gradually to invisibility. The energy required to develop a line here may conveniently be expressed in terms of that needed at the Balmer limit (3646Å) as

$$365/334 \times \nu_1 h = 365/334 \times \mathrm{N}h/4,$$

where ν_1 is the frequency at the Balmer limit, N the series constant, and h is Planck's element of action. Of this energy the amount $\mathrm{N}h/4$ has been developed in capture, leaving the remainder as the original kinetic energy of the electron. Calling this $\mathrm{E}k$, we have

$$\mathrm{E}k = 31/334 \times \mathrm{N}h/4,$$

substituting the numerical values: $h = 6{\cdot}547 \times 10^{-27}$ and $\mathrm{N} = 3{\cdot}290 \times 10^{+15}$,

$$\mathrm{E}k = 5{\cdot}00 \times 10^{-13}. \quad . \quad . \quad . \quad . \quad (1)$$

This is the amount of kinetic energy which must have been possessed by the electron before coming under the action of the capturing nucleus in order that it should be able to develop a line at 3340Å.

[7] *Phil. Mag.*, 26, 17, 1913.

If we regard the speed of the electron as having been acquired through intermolecular reactions making for the equipartition of energy, the above quantity should be comparable with the energy of molecular agitation. For a temperature of 1000° Abs. the mean kinetic energy of a molecule is

$$E(1000) = 2{\cdot}06 \times 10^{-13}. \quad . \quad . \quad . \ (2)$$

Comparing (1) and (2) it is apparent that a gas temperature of about 2500° will be required if an electron of average energy is to develop a line at 3340Å. That position, however, marks the extreme end of the spectrum, and radiation in the neighbourhood is therefore to be regarded as due to the capture of electrons of exceptionally high speed. According to Maxwell's law an appreciable proportion of the molecules have three or four times the mean energy, and it is therefore permissible to divide our 2500° by some such figure as that. It accordingly seems reasonable to assume that 1000° Abs. Cent., or even a less temperature, in the presence of the proper degree of ionisation, would suffice to produce the observed spectrum.[1] The temperature of the chromosphere is of course very much higher than that. With respect to the nebulæ, while we have no general knowledge of their thermal states, it will be recalled that Buisson, Fabry, and Bourget have estimated the temperature of the Orion Nebula to be of the order of 15,000° Cent.[2] In the light of such an estimate, the theoretical requirement of 1000° cannot be regarded as extravagant.

The foregoing considerations related to the suggestions that the electron acquires its speed through equipartition of molecular energy, according to the kinetic theory; that is to say, the spectrum has been regarded as a "temperature effect." It is of course quite conceivable that the electronic velocity might be acquired in some other way, for instance, through the action of an electric field, or photoelectrically, as has been suggested to me by Prof. Frederick A. Saunders in a personal letter. The presence in the Class A stars of absorption beyond the Balmer limit may be taken as evidence that photoelectric ionisation is going on in their atmospheres, and as most of the planetary nebulæ have nuclei that are powerful radiators of ultra-violet light, the suggestion is an attractive one. However, unlike the Class A stars, the nuclei show no perceptible falling off in strength near the head of the Balmer series. If absorption through photoelectric action takes place it is probably higher in the spectrum.

The above remarks refer very largely to the upper, or more refrangible limit of the outlying spectrum; of greater importance is the lower limit, since here contact is established with the line series. The spectrum fades gradually to invisibility at the upper extremity; at the lower the termination is, on the other hand, quite abrupt, and should, according to what has been said, lie at the theoretical limit of the Balmer series. As a matter of fact it has been found, I believe in every case, to be perceptibly to the redward of that point. We recall that this outlying continuous spectrum comes down to the junction from the more refrangible part of the spectrum, and the line series reaches up from the other or redward end. The series limit is at 3646Å, while the edge of the outlying spectrum in the chromosphere, according to Evershed, lies at 3668Å; that is to say, the outlying spectrum overlaps the series limit by about 22Å; more than that, it extends 7Å beyond the highest series line observed by Evershed (3661Å). In the radiation of the nebulæ the end of the outlying spectrum is difficult to measure, but it lies quite certainly to the redward of the Balmer limit. In N.G.C. 7009 it has been estimated to be at about 3650Å, in other nebulæ it is at a greater wave-length. More marked is the discrepancy for the absorption spectrum in the Class A stars. Thus in the spectrum of α Cygni the absorption spectrum may be said to begin at 3710 ± Å, and to reach full strength at 3660 ± Å,[3] while for Vega[4] the corresponding positions are 3800 ± Å and 3710 ± Å. In the latter case we have then the beginning of absorption 150Å to the redward of the series limit, a disparity between theory and observation that might raise a doubt as to whether the absorption bears in reality any relationship to the Balmer series. A consideration of the influence of density will, however, show that an inequality of that order is to be expected.

It is probably significant that in the spectra of α Cygni and of Vega the last of the recorded series lines falls in each case in the neighbourhood of the point where the outlying absorption attains its full value. Thus for Vega the series is lost at 3687Å, and the estimated position of the attainment of full absorption is 3710 ± Å; for α Cygni the highest line is 3668Å, with full absorption estimated to begin at 3660 ± Å. The estimates of the position at which full absorption begins are difficult to make, and the positions given are only roughly approximate, but it is quite evident that the series of dark lines which lie to the redward, and the continuous spectrum which extends in the other direction, merge one into the other, and that the second begins at the *actual* and not at the *theoretical* limit of the first.

The inference that the continuous spectrum should begin at the theoretical limit is based on the assumption that the atomic orbits extend to infinity. Bohr has pointed out that the size of the orbit system is necessarily limited by the density of the radiating gas, and has explained the absence of lines of a very high order as a consequence. Applying this consideration to the theory of the outlying spectrum it seems necessary to substitute for the "orbit at infinity" adopted in our former reasoning, the largest orbit in effective operation. Into the atomic system, as circumscribed by this orbit, electrons may be conceived to enter with speeds from zero upward. Now an entering electron of speed zero has less energy than one moving in the outer effective orbit—less by just the kinetic energy of orbital motion. In dropping into the second orbit therefore it sets free a smaller amount of energy, and consequently produces a line of lower frequency (or greater wave-length) than that of the series line which corresponds to the outer effective orbit. But the line formed by this electron must mark the more refrangible edge of the outlying continuous spectrum. We should, therefore, expect the continuous spectrum to begin somewhere on the less refrangible side of the highest visible member of the Balmer series. In other words, there should be an "overlapping" of the bright-line and continuous spectra such as is actually found. The margin of overlap should be proportional to the kinetic energy of the electron in the outer effective orbit, and on this assumption is expressible by the relation:

$$\nu_2 - \nu_3 = \nu_1 - \nu_2,^5 \quad . \quad . \quad . \quad . \ (3)$$

[1] A higher estimate of the required temperature was given in the earlier paper. I have not at hand the computations on which it was based, but it seems to have been affected by some numerical error, probably the use of N in place of N/4 for the coefficient of h in the equations preceding (1) of this paper.

[2] *Astrophys. Jour.*, 40, 258, 1914.

[3] *Lick Obs. Bull.*, 10, 103, Fig. 1.

[4] *Publ. Lick Obs.*, 13, 257, Fig. 2. The positions for both Vega and α Cygni are scaled from the intensity curves in the respective references. They are subject to great uncertainty. Compare stellar intensity curves by Hartmann, *Phys. Zeit.*, 18, 431.

[5] The expression follows at once from the frequency-energy relation assumed by Bohr. Let the nth be the largest effective orbit of one of his atomic systems; then for the highest line we have:

$$\nu_2 = N(1/2^2 - 1/n^2).$$

The second term in the parenthesis represents the energy lost during the

where ν_1 is the frequency at the theoretical limit of the Balmer series,
ν_2 is the frequency of the highest line that can be formed,
ν_3 is the frequency at the redward edge of the outlying spectrum.

This expression tells us that, expressed in frequencies (and the relation holds approximately for wave-lengths), the margin of overlap of the continuous and line spectra should be equal to the interval between the highest *observable* line of the Balmer series and the theoretical limit.

There are two factors tending to modify the above conclusion. One is that, by the kinetic theory, comparatively few electrons of approximately zero velocity are to be expected. Since these determine the redward edge of the outlying spectrum, that edge should be faint, and the effective limit might be of slightly less wave-length. The other is the fact that all the atomic systems will not at any one instant be reduced by molecular interference to outer orbits of exactly the same order. In these circumstances we should expect the large systems to determine the highest visible lines, and the small ones to establish the redward edge of the outlying continuous spectrum. The effect here would be to introduce a "blurring" factor, and increase the overlap. While these two factors operate against each other, it seems quite impracticable to attempt an estimate of their net effect.

To check the conclusions, the data on the emission spectrum of the chromosphere and the absorption spectra of α Cygni and Vega are collected in the accompanying table. Unfortunately the emission spectra of the nebulæ have not been measured accurately enough to establish their limits. In our theoretical discussion we have regarded the problem from the point of view of emission, and it is perhaps not entirely justifiable to check the conclusions through recourse to absorption spectra, for absorption and emission cannot, in such a case, be regarded as exactly complementary. It is necessary, however, to use the stellar spectra, since, with that of the chromosphere, they constitute the only radiations that have been sufficiently well observed.

Source.	Highest line of Balmer series. Observed.	Commencement of continuous spectrum. Observed.	Computed.
Chromosphere (em.)	3657*	3668	3668
α Cygni (abs.)	3668	3700 ±	3691
Vega (abs.)	3687	3800 ±	3729

* The most refrangible line observed by Evershed was 3661Å. Mitchell, on the occasion of the 1905 eclipse (*Astrophys. Jour.*, 38, 431, 1913: also Publ. Leander McCormick Obs., 2, 49), photographed six additional lines, the highest being at 3656.8Å, the value adopted here. Evershed's plates were taken with a prism spectrograph and Mitchell's with a grating instrument of considerably greater power. The greater extent of the latter's spectrum is no doubt due to that fact.

The last column contains the positions of the lower edge of the outlying spectrum computed from the frequencies of the highest visible lines, using equation (3). The discrepancy between the observed and derived values for Vega is rather large and undoubtedly exceeds the error of measurement. It should be remembered, however, that in the atmosphere of a star absorption must take place throughout a considerable range of density, corresponding to different levels. The higher lines of the series, on which the computations rest, probably originate in the upper and rarer atmosphere, where the conditions are favourable for their formation, while we should expect the edge of the outlying spectrum to be determined in a region of comparatively high density. This would account for a divergence such as the one shown. Considering the number of extraneous factors that have a bearing on the problem the agreement is probably as good as might be expected. The measurements show the progress of the edge of the outlying spectrum toward the redward as the higher members of the Balmer series fade out, and this is in general accord with the theoretical deductions.

transfer from infinity to the *n*th orbit. This is also equal to the kinetic energy of the electron due to motion in its orbit, so that an electron at rest at the *n*th orbit will have lost twice that amount. Therefore

$$\nu_3 = N(1/2^2 - 2/n^2).$$

Remembering that $\nu_1 = N/2^2$, the relation (3) follows.

Summary of Conclusions.—The outlying continuous spectrum found in certain celestial spectra beyond the limit of the Balmer hydrogen series is, as was suggested by Evershed, almost certainly due to hydrogen. It should be more completely studied astronomically, and serious effort should be directed toward developing it in the laboratory, on account of its theoretical interest and of its bearing on astronomical problems.

The spectrum is explicable, on the basis of the Bohr theory, as resulting from a change of state, as between a free electron and one in the second orbit. Bohr's original application of the principle to the case of absorption through photoelectric action on hydrogen atoms, is extended to the conception of emission as resulting from the capture of free electrons by hydrogen nuclei.

Theory and observation are in accord in placing the beginning of the outlying spectrum, not at the theoretical limit of the Balmer series, but to the redward of it, the amount of the displacement being greater as the number of observed series lines is less.

It seems possible to account for the spectrum on the basis of either thermal or electrical excitation. Regarded as a heat effect, it indicates for the planetary nebulæ a temperature of the order of 1000° Abs. Cent. or more. (The figure is not, however, offered as an estimate of the temperature of the nebulæ.)

Discoveries in Tropical Medicine.

I HAVE never thrown any doubt upon the influence of the suggestions made by Manson to Ross which led to the close study by Ross of the carriage of the malaria parasite (of both birds and man) by mosquitoes, and the discovery by him that mosquitoes of the kind known as Anopheles and not those of the kind known as Culex are the "intermediate hosts," in which the parasites causing malaria in man undergo necessary and remarkable stages of their development.

I was a member of the Committee of the Royal Society with which Ross was in constant communication during his work in India, and followed that work step by step in the reports sent home by him. My knowledge of the work of Laveran, of Labbé, Danilewski, and of Celli and of Grassi and the Italian school does not support the claims to "discovery" put forward on behalf of Manson by some of his friends. They are exaggerated and inaccurate—though Manson's influence and enthusiasm need no such mistaken advocacy in order to receive recognition.

It is the fact, in spite of assertions to the contrary, that Manson did *not* discover the part played by the mosquito in the transmission of *Filaria sanguinis hominis*. Important details as to the part played by the mosquito—of whatever kind—in that transmission have yet to be ascertained. They are still—at the present moment—a subject of investigation.

The kind of statement put forward in order to do honour to Manson, but really of a misleading nature, is exemplified in the following from Dr. Sambon's letter in NATURE of May 27. He writes: "Sir Ray Lankester ignores Manson's brilliant interpretation of the 'flagellating' malarial parasite, looked upon by the Italians as a form of degeneration; by Manson as the prelude to a further all-important developmental stage outside the body of man." The reader of Dr. Sambon's letter would suppose that Manson had in this matter had "a happy thought" and had put forward a successful speculation. Such is not the case. The nature and significance of the flagelliform bodies developed by the malaria parasite were first discovered by Dr. W. G. MacCallum, of the Johns Hopkins University, Baltimore, and published by him at the meeting of the British Association in Toronto, August 1897, and more fully set forth with admirable illustrations in the *Journal of Experimental Medicine*, vol. iii., 1898. He describes the rapid formation of these bodies in the Halteridium of birds (crows) as others had already done both in that case and in the malarial parasites of man. What is of capital importance in MacCallum's paper is the careful description and drawings of the active—even violent—union of the liberated flagelliform bodies with certain granular spheres or female gametes. A single flagelliform body was thus seen to fuse with one female gamete. MacCallum, having once recognised this sexual process, observed it daily, and then observed the same process in the æstivo-autumnal parasites taken from two cases of malaria in a human subject.

In discussing the significance of his discovery, MacCallum writes that the whole Italian school believed the flagelliform bodies to be due to degenerative changes. "Manson," he writes, "as is well known, has advanced the idea that the flagellate bodies represent the forms in which the parasite exists outside the human body, that the flagella penetrate from the stomach into the body of mosquitoes which have sucked the blood of infected human beings, and that, after a further unknown process of development, they come again (through the water in which the mosquitoes deposit their eggs and die) into the human body." This and other suppositions were entirely set aside by MacCallum's discovery. MacCallum insists that Manson's idea is not based on any observations, but is pure hypothesis! Manson's interpretation of the flagellating malarial parasite was, though erroneous, a legitimate hypothesis, but it certainly was not "brilliant," although we are asked by Dr. Sambon to regard it as being so. E. RAY LANKESTER.

The Isotopes of Tin.

THE insensitivity of the photographic plate in recording positive rays when compared with its sensitivity to light has long been observed, and has been accounted for by the fact that the action of positive rays is purely a surface effect. There has, therefore, always been the hope that considerable improvement could be made in this direction by increasing the concentration of the bromide particles on the surface of the gelatine. This hope has now been realised to some extent by the use of a method which, I understand, has been devised for the production of Schumann plates. It consists essentially in dissolving off more or less of the gelatine by means of acid. I have not yet succeeded in obtaining certain or uniform effects, but in the most favourable cases the sensitivity of the "Half Tone" plates used in the mass-spectrograph has been increased ten to twenty times without seriously altering their other valuable properties.

The immediate result has been the definite proof of the complex nature of the element tin which had been previously suspected (*Phil. Mag.* xlii. p. 141, July 1921). Tin tetramethide was employed, and a group of eight lines corresponding approximately to atomic weights 116 (c), 117 (f), 118 (b), 119 (e), 120 (a), 121 (h), 122 (g), 124 (d) was definitely proved to be due to tin. This conclusion was satisfactorily confirmed by the presence of similar groups corresponding to $Sn(CH_3)$, $Sn(CH_3)_2$ and $Sn(CH_3)_3$. The intensities of the various components indicated by the letters in brackets agree quite well with the accepted chemical atomic weight 118·7, and incidentally preclude the possibility that any of the lines, with the possible exception of the extremely faint one at 121, are due to hydrides.

The spacing of these eight lines, which are only just resolved, show that their differences are integral to the highest accuracy, but the lines themselves compared with known lines on the plate give atomic weights always tending to be 2 or 3 parts in 1000 too light for the above whole numbers. That this remarkable divergence cannot be explained as experimental error is very strongly indicated by the following consideration. The discharge tube had been used previously to investigate some very pure xenon. The line due to $Sn^{120}(CH_3)$ should therefore have appeared exactly halfway between the two strong xenon lines 134, 136. It was actually quite unmistakably nearer the former, so much so that the two were only partially resolved. The same irregular grouping repeated itself in another portion of the field in the following spectrum. It seems, therefore, difficult to resist the conclusion that the isotopes of tin have atomic weights which are less than whole numbers by one-fifth to one-third of a unit of atomic weight, but satisfactory settlement of this important point will probably have to be deferred till a more accurate mass-spectrograph has been made.

Incidentally I may add that the presence of the two faint components of xenon 128 and 130 previously suspected has now been satisfactorily confirmed.

The Spiracular Muscles of Hymenoptera Aculeata.

I DESIRE to direct the attention of entomologists to a recently discovered muscle (see *Bee World*, vol. iii. p. 282, April 1922) present in the honey bee (*Apis mellifica*), and probably in many others of the Hymenoptera Aculeata.

The abdominal (respiratory) muscles of *Apis mellifica* were described by Carlet (*Comptes rendus*, Acad. Sci., Paris, 1884, vol. 98, p. 758). His list is incorrect; it misplaces the posterior attachment of the internal oblique muscle and omits the interdorsals and the spiracular muscles. To the latter it is desired to direct attention here. They run from the lateral sternal apophysis to the larger of the two cones of the spiracle on the tergum of the same segment. Thus, when the abdomen is expanded, this muscle is under tension, and will pull open the closing apparatus of the spiracle. During expiration, the abdomen is contracted; the spiracular muscles will therefore be slack during this process, and it appears highly improbable that the spiracles actuated by them can open during expiration. The expired air must therefore pass out of the system mainly through the thoracic spiracles; a fact which renders comprehensible

the immediate ill effects of blocking of the prothoracic spiracles by *Tarsonemus woodi*, the causal parasite of Isle-of-Wight (Acarine) disease.

Spiracular muscles (apparently similar in function to those of *Apis mellifica*) have been found in *Vespa sp.*, *Bombus sp.*, and a wild bee (? *Prosopis*). In a modified form, they are present in *Formica sp.*, being there apparently attached to the anterior edge of the tergum, and not to the sternal apophysis.

To see these, as well as the other abdominal muscles of the bee, I may mention that material preserved in equal parts of methylated spirit and formalin, deeply coloured with light green so as to stain the muscles, is excellent. Dissect in water.

Symbiotic Bacteria and Phosphorescence.

IN Prof. Gamble's review of Buchner's "Tier und Pflanze in intrazellularer Symbiose" (NATURE, May 6) reference is made to the work of Pierantoni, according to whom the luminous organs of cephalopods are "essentially cultures of bacteria in media suitable for their nutrition and in situations favourable for obtaining oxygen."

The claims which are made for the existence of similar symbiotes in fire-flies and many other phosphorescent organisms may be extravagant, but Newton Harvey's recent announcement in the Year-book (No. 20 (1921), pp. 196-97) of the Carnegie Institution of Washington is exceedingly important in this connection. Harvey worked on two fishes with very large luminous organs—Photoblepharon and Anomalops—at Banda in the Dutch East Indies. He found bacteria always present in the organs, and emulsions of these organs behaved exactly like emulsions of luminous bacteria. The light continues night and day without ceasing, independently of stimulation. This is characteristic of the light due to luminous bacteria and fungi alone among organisms. Harvey did not succeed in growing the bacteria artificially, however; but considering the conditions under which they apparently live, this would, naturally, be a task of great difficulty. Dahlgren (see the same reference) seems to have confirmed Harvey's discovery in other fishes.

Luciferin and luciferase could not be demonstrated, which is also characteristic of luminous bacteria.

Stone Preservation.

MAY I throw out a suggestion, which, I believe, is new, as to a method for preserving decaying sandstones from further decay?

Certain compounds of alcohol-radicles with silica, when exposed to moist air, hydrolyse, deposit hydrated silica in a coherent form, and thus act as a cement. The ether can be thinned with alcohol, and is a very stable body so long as it is not exposed to moisture, and if a piece of rotten sandstone is treated with it, in the course of a few days the sandstone hardens up and the resulting cement resists the attacks of acids.

Unfortunately, this process does not solve equally well the important problem of preserving limestones, since, though it binds the particles of limestones together, it does not protect the particles themselves from attack.

A. P. LAURIE.

Heriot-Watt College, Edinburgh, May 31.

Oscillation Circuits for the Determination of Di-electric Constants at Radio Frequencies.

DURING the last year or so a number of investigators have made use of the underlying principles of the heterodyne system of wireless telegraphy in the determination of di-electric constants. The extreme sensitivity of this method, and its freedom from some of the weaknesses which have rendered precise measurements by the older methods difficult of attainment, are rapidly increasing its popularity, and any changes which make for simplicity and for still greater certainty are of interest.

For no apparent reason circuits of the type used only for receiving signals have, so far as the writer is aware, been employed, though greater efficiency is to be expected from the use of a transmitting circuit in conjunction with such a receiving circuit generating local oscillations. In either case it is preferable that the oscillation circuit, of which the condenser containing the material under investigation forms a part, should not rectify, as rectification is necessarily accompanied by distortion of wave form.

Instead of using the two electrically insulated circuits hitherto employed the writer prefers that shown in Fig. 1, in which simple transmitting and receiving circuits are combined in such a way that

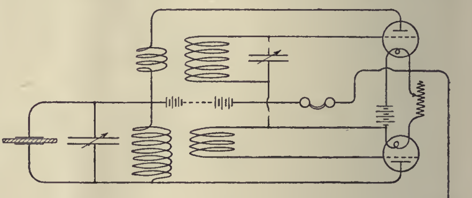

FIG. 1.

oscillations of two different frequencies can be generated although both valves are fed from the same filament-heating and anode batteries. An additional reason why only one valve should be used for rectification with this particular arrangement lies in the fact that, if both valves were rectifying, the unidirectional pulses of current of audible frequency produced in each of the circuits by the rectification of the interfering oscillations would tend to produce a steady current, since they would be quite out of phase with each other.

As is well known to workers who have had experience of apparatus of this kind, changes in the value of the filament-heating current by altering what is virtually the resistance of a valve affect, to a certain extent, the frequency of the oscillations generated. This trouble can be lessened to a very great extent by taking the heating current for both filaments from the same battery of accumulators. The filaments can be connected in parallel, but there is more to be gained by connecting them in series, as will be apparent from the figure. It will be seen that, although the two grids are at the same potential with respect to earth, their potentials with respect to the heated filaments are quite different; in the case of the valve shown in the lower half of the figure the potential difference is such that it can "oscillate" only, while the other valve can both oscillate and rectify.

In conclusion, it should be stated that this letter is written with the kind permission of the Director of Artillery, War Office.

A Century of Astronomy.[1]

By Prof. A. S. Eddington, F.R.S.

THE celebration of a centenary is an occasion for retrospect over the past and for hopeful outlook towards the future. We have here representatives of many different sides of astronomy who view it from many different aspects, and I should not be surprised if there are wide differences of opinion as to which are the outstanding landmarks in these hundred years. Like selecting the hundred best books, the selection of, let us say, the six great landmarks of astronomical progress in the century is a pastime which need not be taken too seriously. I shall venture to try my hand at a selection:—

(1) 1839. The first determinations of stellar parallax of 61 Cygni and α Centauri, giving for the first time a definite idea of the scale of the stellar universe.

(2) 1846. The discovery of Neptune. An event perhaps more highly celebrated outside astronomical circles than among professional astronomers, but producing an incalculable moral effect.

(3) 1864–68. The early spectroscopic discoveries of Huggins and Lockyer, and the rise of spectroscopic astronomy.

(4) 1882–87. The beginnings of stellar photography, starting with Gill's photograph of the great comet of 1882 and leading to the inception of the astrographic chart in 1887.

(5) 1904. Kapteyn's discovery of the two star-streams, the beginning of the modern era of investigations of the sidereal system.

Coming to events so near to the present that we cannot yet put much trust in our perspective, I would very tentatively include

(6) 1920. The measurement of the angular diameter of Betelgeuse by Michelson's interferometer method. I would not venture to predict how great or how immediate may be the influence of this last on the progress of astronomy; but it seems to me to be worthy of a place in this select list as a triumph of scientific achievement which is second to none. It is one of those signal instances which convince us that the word "impossible" must be banished from the vocabulary.

This is a record of continuous advance—not in great waves followed by periods of exhaustion. A new impetus has always been found before the last one has begun to fail. Even the allied science of physics has not, I think, had such a continuous record. I am told that there was a period shortly before X-rays and electrons came to the fore, when the physicist had given up anticipating any radical advance; he thought that the big discoveries were already garnered; and the feeling, so present with us to-day, that we are on the verge of something greater than our dreams can shape, had not yet disturbed his placid progress.

The centre of most rapid progress has shifted from time to time, and the various branches of astronomy have had their ups and downs. I suppose that in recent years the department of planetary astronomy has been in the depression of a wave. At least it seems to be so in comparison with the more sensational progress in our knowledge of the sun and stars. Whether we regard the physical observation of the surfaces of the planets or the study of their motions, the openings for advance seem to be few and difficult. But the depression has by no means reached stagnation. We have the remarkable advance in planetary photography, exhibited at several recent meetings of the Society; the discovery of new satellites, including Jupiter's two pairs of twins, and the specially significant phenomenon of the retrograde motion of the outermost satellites of Jupiter and Saturn; the determination of the rotation period of Uranus by Slipher; and the Trojan group of minor planets, the principal merit of which is that they have beneficently prevented the once great science of dynamical astronomy from growing altogether rusty. Renewed interest is added to the exact and regular observation of the positions of planets by Einstein's explanation of the anomalous motion of Mercury; the same observations reveal interesting irregularities in the longitudes of the planets which perhaps reflect inequalities in the rotation of the earth as standard time-keeper. These observations, which else might have seemed to be mere survivals of traditional routine, are seen to be full of importance for the future; and for the same reason we welcome the revival of observations of occultations of stars by planets. On the theoretical side, we have Taylor's important investigation of tidal friction in the Irish Sea, which, true to its name, is responsible for a considerable proportion of the friction and dissipation of energy on this planet; and Jeans's researches have given us new ideas of the origin of the planets which attend the sun, and of the singular (perhaps even unique) character of this system. Many other researches in this field could be mentioned. If the department of planetary astronomy is now the Cinderella of our science, she yet has dreams that her Prince is waiting for her.

It is startling to-day to read a passage from Huxley's "Essays" which runs:—"Until human life is longer and the duties of the present press less heavily, I do not think wise men will occupy themselves with Jovian or Martian natural history." Martian—and I almost fear to mention it—lunar natural history are no doubt thorny subjects, but notwithstanding Huxley's censure, probably the most sceptical among us would admit that the observation of seasonal changes of what is presumably some kind of vegetation on Mars is a recognised astronomical pursuit.

In reviewing the general advance of astronomy during the century, we cannot but be struck by what I may call its *centrifugal* tendency—the tendency to leave the little system ruled by the sun and penetrate deeper and ever deeper into the vast world outside. In the older books, the author leads us deliberately through the planets one by one, and it is with difficulty that the account of the stellar universe can be spun out to any respectable length. Before the first meeting of this Society in 1820 an introductory address was circulated, which contains the paragraph:

Beyond the limits of our own system, all at present

[1] From the presidential address delivered before the Royal Astronomical Society on May 30.

is obscurity. Some vast and general views on the construction of the heavens, and the laws which may regulate the formation and motions of sidereal systems, have, it is true, been struck out; but, like the theories of the earth which have so long occupied the speculations of geologists, they remain to be supported or confuted by the slow accumulation of a mass of facts; and it is here, as in the science just alluded to, that the advantages of associated labour will appear more eminently conspicuous.

While much obscurity still remains, this vast territory has been definitely annexed and occupied. From the planetary system we have passed to the stellar system; and I am not sure if even the study of that great aggregation of stars which we used to think was the whole universe is not becoming a little old-fashioned, and the really up-to-date young astronomer would refuse to bother about anything nearer than a globular cluster. At least it is one of the most startling features of recent research that so much exact knowledge has been obtained of the conditions of stars in globular clusters, not one of which is nearer than 10,000 light-years—knowledge which in many respects far surpasses in precision that which it has been possible to obtain for the much nearer denizens of our own star-cloud.

It may be of interest to examine how this centrifugal tendency is reflected in our Monthly Notices, and I have prepared a table to show how the subject-matter of the papers has changed. The figures claim no great accuracy, because it is often difficult to classify the papers clearly and uniformly; and, of course, the statistics do not distinguish important papers or long-continued observations from trivial notes and controversies. But on the whole the figures seem to be truly representative.

CLASSIFICATION OF PAPERS IN MONTHLY NOTICES, R.A.S.

	1840. (3 years.)	1860.	1880.	1900.	1919.	1920.
Instrumental . . .	6	4	11	3	6	5
Solar System . . .	39	69	73	56	14	21
Stellar universe. . .	18	13	22	21	49	40
Geodesy, navigation, seismology, etc. . . .	14	3	6	..	5	11
Ancient observations .	2	1	1	..	1	1
Mathematical (not classed above)	..	..	2	..	1	12
(Ditto, omitting ephemerides, tabular observations, etc., and formal reports of phenomena.)						
Solar system . . .	9	38	34	21	11	17
Stellar universe. . .	7	11	16	12	33	32

It appears that the serious change did not begin until after 1900. Although it shows itself quite suddenly in the statistics, it had been steadily prepared for during a long period. It must be remembered that much of the heaviest work on the stars is by its nature excluded from the Monthly Notices, and appears only in the more voluminous publications of observatories. Solar, lunar, and planetary observations are not usually too bulky to include. Much long-continued preparation for proper motions, spectral classification, radial velocities, stellar magnitudes, etc., began to come to fruition between 1900 and 1910. But I think the great impetus to sidereal astronomy came from Kapteyn's discovery, which I have mentioned among the six landmarks of the century. The two star-streams were the first taste of the many amazing results contained in the statistics collected or being collected. They were the first indication to us of something like organisation among the myriads of stars. Paradoxical as it may seem, the duality of the stellar system was the first clear indication to us of its unity. In the earlier years most of the papers classified in the table as referring to the stellar universe dealt with particular objects—variables, rapid binaries, Novae. It was a period of individualism. But from 1900 onwards the great democracy of the stars was brought into prominence, and a great wave of stellar socialism began. Kapteyn is the typical pioneer of a numerous body of investigators who view the heavens in the spirit of Xavier le Maistre in "Voyages autour de ma Chambre":

> The most brilliant stars have never been those which I contemplate with most pleasure; but the tiniest ones, those which, lost in immeasurable distance, appear only as barely perceptible points, have always been my favourite stars.

Yet perhaps in the very latest years there has been a reaction towards individualism. The statistical mill is no longer working overtime. The queer stars, such as Cepheids, runaway dwarfs, special binaries, are beginning to contribute more largely to the general perfection of the whole scheme. Strange objects which persist in showing a type of spectrum entirely out of keeping with their luminosity, may ultimately teach us more than a host which radiate according to rule.

It is noticeable that in the early years the disproportionate excess of papers on the solar system compared with the outside regions of the universe was not so marked as it afterwards became. This is no accident. The founders of the Royal Astronomical Society, while confessing almost complete ignorance of this domain, were resolved that it should be attacked, and had the conviction that patient research would make the advance possible. Indeed, it was just this which was placed among the most prominent reasons for banding together. With regard to eclipses, planets, and comets, it might be possible to struggle along individually; but the problems involving thousands of stars were too vast for one man or for one generation. They saw that the observations were being piled up, but without uniformity and without system. To quote again from their address:—

> One of the first great steps towards an accurate knowledge of the construction of the heavens is an acquaintance with the individual objects which they present: in other words, the formation of a complete catalogue of stars and of other bodies, upon a scale infinitely more vast than has yet been undertaken, and that shall comprehend the most minute objects visible in good astronomical telescopes. To form such a catalogue, however, is an undertaking of such overwhelming labour as to defy the utmost exertions of individual industry. It is a task which, to be accomplished, *must* be divided among members; but so divided as to preserve a perfect unity of design. . . . The intended foundation of an Observatory at the southern extremity of Africa, under the auspices of the Admiralty, may serve to show the general sense entertained of the importance of this subject, and the necessity of giving every possible perfection to our catalogue of the fixed stars. Deeply impressed also with the importance of this task, and fully aware of its difficulty, the Astronomical Society might call upon the observers of Europe and of the world to lend their aid in its prosecution. Electromagnetic Theory. By OLIVER HEAVISIDE, F.R.S., Hon. M.I.E.E. Three Volumes. Demy 8vo. £5 : 5s net the set.

We have great pleasure in announcing the reissue of Oliver Heaviside's great classic, which has been unprocurable for some time in a complete form. The edition is limited to 250 sets, of which 100 are for America. This issue must be taken as the final one, at least for many years.

The Institution of Electrical Engineers, at their recent Jubilee Commemoration, passed a resolution which concluded : "They are convinced that, as now so in the future, the name of Heaviside will be one of the names which will rank among those of the great founders of the science of applied electricity."

Insect Pests of the Horticulturalist: Their Nature and Control. Vol. I: Onion, Carrot and Celery Flies. By K. M. SMITH, A.R.C.S., D.I.C., Adviser in Agricultural Entomology, Manchester University, and J. C. M. GARDNER, A.R.C.S., D.I.C., F.E.S. With 41 Illustrations. Crown 4to. 7s 6d net.

In the present volume we get the benefit of the collaboration of the Society of Horticultural Technology and the Technical Committee of the Chamber of Horticulture in investigating and making known the life history and habits of three very serious pests of the commercial grower. The information is offered in a form capable of being understood both by students and by practical growers, but its primary appeal is to the scientific worker.

RAY TRACK APPARATUS

A modification of Mr. C. T. R. Wilson's Cloud Expansion Apparatus, due to Mr. T. Shimizu. By means of a reciprocating piston a series of expansions is obtained at the rate of 50–200 per minute, cloud tracks being formed at each expansion and dissipated during the compression stroke by applying an electrostatic field. The tracks can be observed visually or photographed.

institutions be formed in other countries, the Astronomical Society (rejecting all views but that of benefiting science) would be ready and desirous to divide at once the labour and the glory of this Herculean attempt, and to act in concert together in such manner as should be judged most conducive to the end in view.

It is largely the Herculean nature of the task before us which has led to astronomy being to-day (whether for good or ill) the most highly organised of the sciences.

The accomplishment of these objects has not been rapid. A passage in the First Annual Report of the Council mentions as one of the greatest desiderata a means of determining the apparent magnitudes of the stars, and ascertaining "a correct scale whereby astronomers may be enabled to express themselves in one common language on this subject." The lapse of a century has not quite sufficed for the completion of this uniform scale; but the main difficulties have been surmounted, and the time is very near now when all astronomers will be able to express themselves in a common language in regard to stellar magnitudes, both visual and photographic.

The foundation of our Society on January 12, 1820, caused a ripple in the aether which has spread out ever since in widening circles. To-day that ripple embraces about 5000 of the fixed stars. The remaining thousand million or so are still outside. Though a good many of the best-known stars must by this time have received the tidings, 90 per cent. of the naked-eye stars are still in ignorance. We should like to think that the stars of the morning sing together with joy on this our Centenary; but the cold truth must be faced that not 1 in 100,000 can yet have heard of our birth. But we shall look out on the heavens again to-night with renewed enthusiasm and joy; and if from the majority of the stars we can expect no more than an unrecognising stare, there are half-a-dozen old favourites which—we may fairly be persuaded—will give us an answering twinkle.

X-Ray Studies on the Crystal Structure of Iron and Steel.

At the annual meeting of the Iron and Steel Institute last year, Dr. Westgren presented a paper on some X-ray crystallographic investigations on iron and steel. At that time the photograms on which his conclusions regarding the crystal structure of the steel components were based were not very clear, and were not published. Moreover, owing to spontaneous crystal growth at high temperatures, the photogram of gamma iron at 1000° C. did not show any continuous lines, but only a few spots. Since then, Dr. Westgren has continued his investigations and improved the experimental arrangements, and in a paper published with Mr. Phragmen at the corresponding meeting of the Institute on May 5 last, he showed photograms of very great interest and significance.

The X-rays were produced in a tube of the Seigbahn type. Difficulties had previously been experienced in obtaining vacuum-tight bronze tubes which composed the metal body. A more suitable material has been found in Skefko ball-bearing steel, which is remarkably free from slag inclusions and heterogeneities. The anti-cathode was cut off perpendicularly to its axis, and in order to get the characteristic X-rays of iron, which are very convenient for these investigations, an iron plate was soldered on to it. Round the radiating surface five windows were made. The tube therefore gave five beams, and exposures could be made in five cameras simultaneously. The tube was evacuated by the combination of a mercury vapour jet pump and a mercury diffusion pump of the Volmer type. Special arrangements were made for maintaining the vacuum of the desired quality. The tube was usually charged with 45,000-50,000 volts and run with 10-12 milliamperes.

In investigating the crystal structure of pure iron at different temperatures, a wire (0·3 millimetre diameter) of vacuum-melted electrolytic iron containing 99·98 per cent. of the metal was investigated. Arrangements were made for rotating this three or four times per minute during exposures. Photograms were taken at the ordinary temperatures, and at about 800°, 1100° and 1425° C., which gave information of the structures of the iron in the alpha, beta, gamma and delta ranges (Fig. 1). The time of exposure was 2½ hours. The lines in the photograms obtained at the ordinary temperatures are clear and sharp, but in the higher ranges of temperature investigated they appear broad and not very distinct. The author explains this as due to the fact that the iron wire at temperatures of about 1400° C. is extremely pliable. Its position, therefore, changed somewhat during the exposure. Moreover, he found it very difficult to keep the temperature of the wire steady in the delta iron range. If the temperature was maintained at 1450° C., *i.e.* within about 70° of the melting point, the wire became so soft that it could not stand the torsion. The temperature, there-

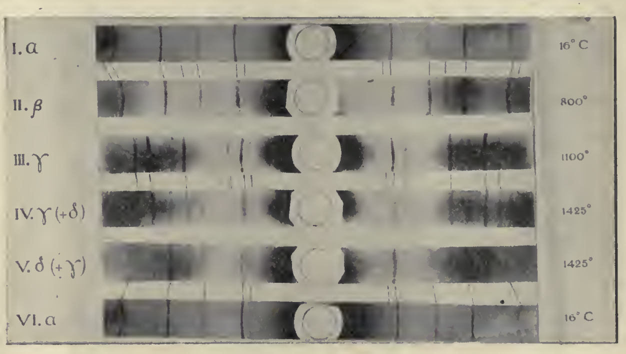

FIG. 1.

fore, had to be kept not above 1425° C., which is near the delta-gamma transformation point. Moreover, it was found necessary to counteract the influence of grain growth at these very high temperatures. For this purpose the temperature was varied every 5 or 10 minutes so as to bring the iron into the range of another modification, *e.g.* in taking the beta iron photogram the temperature was raised from time to time to about 1000° C., and when the gamma and delta irons were investigated the heating current was broken off now and then, so as to let the wire cool down into the alpha range. Photograms of delta iron, which always contained some gamma iron, show, accordingly, lines characteristic both of the delta and gamma varieties.

Experiments carried out on the above lines show that alpha, beta, and delta irons have a body-centred cubic lattice, whereas gamma iron has a face-centred cubic lattice. The former lattice contains an atom at each corner of the cube and one in the centre, the latter has an atom at each corner and also in the centre of each face. It follows, therefore, that although there are generally considered to be four modifications of iron, three of them possess one and the same crystal form. For alpha iron at the ordinary temperature a has been found to be 2·87 Å.U.; at 800° C. it has increased to 2·90 Å.U., and at 1425° C. to 2·93 Å.U. This agrees very well with the known dilatation coefficient of alpha iron. The heat expansion of gamma iron also manifests itself in the increase of alpha-gamma from 3·63 Å.U. at 1100° C. to 3·68 Å.U. at 1425° C., which agrees well with the fact that the coefficient of gamma iron is greater than that of alpha iron.

At first sight it appears rather startling that the transformation which takes place at A_3 (beta to gamma) is reversed at the higher temperature A_4 (gamma to delta). However, the diagrams of Weiss and Foëx which the author reproduces, showing the change of magnetic susceptibilities of iron, indicate that alpha, beta and delta iron probably possess one and the same structure. Evidence as to the existence of delta iron has gradually been accumulating during recent years, and this modification can now be regarded as being well established. Henceforth, it must take its place in the iron-carbon equilibrium diagram.

Great interest attaches to the authors' experiments on the influence of carbon on the space-lattice of iron in hardened steels (Fig. 2). These show that the gamma-iron lattice of austenitic steels is enlarged by dissolved carbon. A steel with 1·98 per cent. carbon has been found to have a somewhat larger lattice when quenched from 1100° C. than from 1000° C. The investigations thus show that carbon has a distorting influence on the lattice, and a further interesting point concerning this effect may be noted. The carbon atoms may be situated in the cavities of the iron lattice, but the author concludes that they are distributed quite irregularly in the austenite crystals. If their deforming influence were of a local nature, the interference radiation would be diffuse. The lines of the photograms of the austenite containing high carbon are, however, very distinct and clear, thus proving that the iron lattice is uniformly deformed.

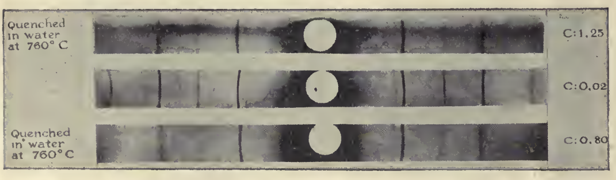

FIG. 2.

Photograms of martensite, the characteristic constituent of hardened steel, show three very faint and diffuse lines, but their cloudiness makes it difficult exactly to determine the position of their intensity maxima. The a-values of the alpha iron in martensite are not, therefore, so trustworthy as those of gamma iron in austenite, but the various modifications of iron in all the four photograms published have given the same value, namely, 2·90 Å.U., which indicates that the alpha iron lattice of martensite is likewise enlarged by the carbon atoms present. On the basis of these results, the authors discuss the deeply interesting question, whether martensite is a two-phase system or a homogeneous solid atom disperse solution. If the iron lattice is uniformly deformed, it seems probable that martensite, like austenite, is a true solid solution of carbon of iron. If, however, the photogram of martensite is identical with that of pure alpha iron, it would indicate that the hardened steel contains a mass of alpha iron particles, free from carbon. The photograms thus far obtained point in the direction of the first of these possibilities, and it seems probable that martensite is a real atom disperse solution. The diffuseness of the line in the photograms gives very important information as to the structure of this constituent. As Scherrer shows, the lines of a Debye-Scherrer photogram get broader and more diffuse in proportion as the crystal powder is more finely divided. No quantitative comparisons have yet been made for martensite, but from a qualitative comparison, of a film of steel (0·80 per cent of carbon), with the photogram of an extremely fine-grained gold colloid, the authors conclude that the steel is as highly disperse as the colloid. The lines of the martensite seem to be about as broad as those in the gold photogram. The ranges of homogeneous lattice in the steel have accordingly, on an average, an extension of about 20 Å.U., and each of them contains only a few hundred atoms.

In the concluding section of their paper the authors publish photograms of the iron carbide, cementite, Fe_3C. This they have found to be identical with the well-known crystal plates of speigel iron. By means of a Laue photogram and investigations of an orientated rotating crystal of speigel, it has been possible to deduce the crystal data of cementite. The authors conclude that it belongs to the orthorhombic system. Its ratio of axes is 0·670 : 0·755 : 1. The dimensions of its elementary parallelopiped are 4·53, 5·11, and 6·77 Å.U. The base group consists of four molecules, Fe_3C, which corresponds to a specific weight of 7·62 for cementite.

Wireless Telephone Receiving Sets.

A NUMBER of patterns of complete wireless telephone receiving sets are being introduced to meet the requirements of the popular broadcasting services which will shortly be put in operation. It is regrettable that there has been a tendency, in striving after simplicity and cheapness, to cut the apparatus down to rather fine limits, resulting in the elimination of adjustments and features which are most desirable for really satisfactory working. Indeed many of the sets being advertised are little better than toys. It is true that reception of a sort is quite possible with elementary crystal sets, but the unskilled user will undoubtedly be better served by the slightly more expensive valve apparatus which is now being made in simple and convenient forms.

We have had the opportunity of inspecting an equipment supplied by the firm of Radio Supplies (236 High Holborn, W.C.1) which is typical of a good class of apparatus of this sort. This firm's M type set, which is sufficient for all ordinary reception, is of the two-valve pattern, one valve acting as detector and the other as amplifier, the latter being in the low-frequency circuit, forming what is termed a note-amplifier. The valves with their filament rheostats, switches, terminals, etc., are mounted on a compact case, but the aerial inductance is carried on a separate stand. In this the convenient arrangement is adapted of obtaining a variable coupling by turning a simple milled head, which alters the relative angular position of the coils in question. Alternative coils, which can easily be plugged into place on the swinging arm, are used for different "bands" of wave-lengths. The fine tuning adjustment is obtained by a very compactly arranged variable condenser, and by this means the apparatus can be tuned to any wave-length from 180 to 30,000 metres.

With the pattern of valve employed a six-volt accumulator is generally used for the filament circuits, and it is recommended that this be of the 60 ampere-hour size, if the apparatus is in daily use for long periods, as then it will not have to be charged more than about once a week. It is, of course, possible in places where there are absolutely no facilities for recharging accumulator cells, to use large dry cells for the filaments. The high-voltage or anode circuits of the valves are supplied by compact multicell dry batteries at voltages from 30 to 70 volts according to circumstances. These are made up in blocks about 8 inches long of 30 cells each, and in view of the very small current taken from them, should last nine months without renewal.

A set of this kind, which complete with a small aerial and every accessory would cost from 25*l.* to 30*l.*, will pick up in addition to telephony, spark, tonic train, or continuous wave signals. Even with an indoor "aerial," the concerts from the Hague are audible all over the room, with an ordinary telephone receiver. The firm also supply larger sets with further degrees of amplification, but for all ordinary work two valves are quite sufficient.

Obituary.

PROF. A. LAVERAN, FOR. MEM., R.S.

FRANCE lost one of her great men of science when Charles Louis Alfonse Laveran died on May 18 at the ripe age of seventy-six. His death, following so closely on that of Sir Patrick Manson, may be said to close one chapter in the history of malaria, the important preliminary chapter which paved the way for the brilliant and far-reaching researches of Ross and the Italian observers.

Laveran was born at Paris on June 18, 1845, his father, a military surgeon, being a professor at the school of Val-de-Grâce. The son followed in his father's footsteps, for, after completing his studies in Paris, he decided to become an army doctor, and matriculated as a medical student at Strasbourg. He graduated in 1867, submitting a thesis on the regeneration of nerves. In 1874 he joined the staff of the Val-de-Grâce School of Military Medicine, and in 1878 was sent to Algeria, where he remained till 1883. It was in this country, at Bône and at Constantine, that he turned his attention to malaria, and carried out the memorable work with which his name will for ever be associated.

As a result of his labours Laveran was appointed, in 1884, professor of military hygiene and clinical medicine at Val-de-Grâce, posts which he held for ten years. Thereafter, for a short space, he was concerned with administrative medical and sanitary work at Lille and at Nantes, but his heart was given to scientific pursuits, and, desirous of continuing his researches, more especially in protozoology, he relinquished his appointments in 1897, and retired with the rank of *médecin principal* of the first class.

Laveran then entered the Pasteur Institute where he soon became a professor. There he remained for the rest of his life, always busy, a tireless investigator who never flagged until age and infirmities conquered even his indomitable spirit, and he was no longer able to use his beloved microscope and pursue those studies to which he had devoted his life to such good purpose. As Prof. Brumpt pointed out in his address to the Academy of Medicine, a failure in Laveran's powers was noticeable after the fêtes in connection with the centenary of that Institution in which he took an active part. The effort exhausted him, and he no longer attended the meetings of scientific societies with his wonted regularity, a sure sign in his case of the approaching end.

Laveran's greatest work, and that which entitles him to a place in the medical Valhalla, was his discovery of the parasite of malaria. In Algiers he commenced his studies on the pathology of that disease, and his attention was specially directed to the characteristic pigmentation of the liver and brain in fatal cases. This had already been recognised, but it was

Laveran who demonstrated pigment granules in certain bodies exhibiting amœboid movements in the blood. These bodies were crescentic or spherical in shape, and he looked upon them as of a parasitic nature, though it was not until 1880, when at Constantine, that all doubts were swept from his mind by his discovery of the phenomenon known as "flagellation of the male crescent." So remarkable were the appearances presented that he no longer hesitated to declare his belief.

As is always the way in this conservative world when something new and strange is revealed, there was much scepticism as to the validity of his findings, but Laveran, who possessed most of the qualities of the successful investigator, was not to be daunted. By a series of careful observations, pathological, clinical, geographical, and therapeutic, he routed his opponents and eventually satisfied the scientific world that his conclusions were well founded.

Laveran shared the view which King advanced in 1883 that human malaria was a mosquito-borne disease, but he had no opportunity of testing the theory, which was finally established as a fact by Grassi, Bignami, and Bastianelli in Italy in 1897 after Ross had, in India, completed his epoch-making work on the transmission of bird malaria by culicines, and had seen the early stages of the development of the human malaria parasite in anophelines.

The Academy of Science set its seal on Laveran's discovery in 1889 and elected him a member in 1895. In 1893 he became a member of the Academy of Medicine, and he also joined the Society of Biology. It was not, however, until the true significance of his researches had been rendered apparent by the work which resulted from them that Laveran's claims to be in the first rank of living men of science were fully recognised. Then, indeed, he was paid the honour which was his due, and among many other distinctions was given the Nobel prize for medicine in 1907.

Together with some of his colleagues Laveran founded the Société de Pathologie Exotique, of which he was the first president, and during the dozen years of his chairmanship the society prospered greatly. In the *Bulletin* of the society many of Laveran's papers were published, and he did much to forward the cause of tropical medicine and hygiene throughout the French colonial possessions.

Laveran, like Manson, inspired others with his enthusiasm, and was an acknowledged leader in his own subjects. He wrote much on malaria, and collected his contributions in the well-known "Traitè de Paludisme" in 1898, of which a second edition appeared in 1907.

His work at the Pasteur Institute was most prolific, and much of it was carried out in collaboration with Prof. Mesnil. Together they produced an important work on trypanosomes and trypanosomiasis, which reached a second edition, and was a mine of well-arranged information. Laveran was well qualified to write on the subject from the laboratory standpoint, for he conducted a great deal of experimental work on trypanosome infection, and tested many remedies with the view of finding a cure for sleeping sickness. Turning his attention to leishmaniasis, he published the first treatise on this subject, the study of which led him to investigate many of the flagellate parasites of man and animals. The sporozoa of animals had earlier attracted his attention, and he investigated the properties of sarcocystine, the first toxin extracted from a sporozoon, and the pathogenicity of which was determined by Pfeiffer.

Considerations of space prevent any full account of Laveran's manifold activities. He was never idle, and no sooner was one piece of work completed than he was busy at another. His conclusions have not always been generally accepted, but he had ever the courage of his convictions, and adhered to his well-considered views with that tenacity which was so strong a feature of his character. In reality a kindly man, he was apt to be considered a trifle brusque by those who did not know him, especially if they trespassed overmuch on his working hours, but he was ever ready to aid the genuine inquirer and also to give credit where credit was due. He was precise and accurate in his work, careful in his writings, and possessed in a very high degree the scientific habit of mind, qualities which enabled him to stamp his personality on whatever he undertook, and will entitle him, for all time, to a foremost place in the ranks of those who have advanced the causes of parasitology and medicine in the tropics. A. B.

DR. J. RENÉ BENOÎT.

THE world of science has suffered a severe loss by the death at Dijon, on May 4, of Dr. J. René Benoît, honorary director of the Bureau International des Poids et Mesures, Sèvres. Dr. Benoît, who was born in 1844, commenced his scientific career in the study of medicine, but, having attained his doctorate, transferred his attention to pure physics, working first in Jamin's laboratory, where he prepared a thesis on the electrical conductivity of metals. After some years in industrial life he joined the Bureau International in 1878 as assistant director to Dr. O. J. Broch, whom he succeeded as director in 1889. It was at the Bureau International that his great work was achieved. His first investigations were related to the improvement of thermometric and barometric measurements, and were followed by very careful experiments directed to the measurement of thermal expansions, particularly with the Fizeau apparatus, which he greatly perfected, and which continued to hold his interest to the end of his career. Dr. Benoît took a large personal share in the work of verifying the principal series of prototype metres, and executed a number of very accurate comparisons of the International Metre with other current standards of length, including the British Imperial Yard and the ancient Toise du Pérou and Toise de Bessel, on which the original French metre and the geodesic measurements of central and western Europe had formerly been based.

In 1891 Prof. A. A. Michelson was invited by the Comité International to carry out at the Bureau his contemplated researches into the relation between the metre and the wave-length of light. Dr. Benoît threw himself enthusiastically into this work, and was closely associated with it throughout. Again in

1906, when MM. Fabry and Perot took up the same investigations by the new method of superposed fringes, he gave them the full benefit of his earlier experience and every assistance in his power. The remarkable concordance (the difference was not much in excess of one part in ten million) between the results of the two investigations is sufficient testimony to the accuracy of the earlier work, and although possibly it must be admitted that fortune played its part, and that the absolute accuracy was not quite so high as the agreement between the two results appeared to indicate, an accuracy not inferior to one part in a million may, in any case, safely be considered to have been attained.

Dr. Benoît was associated also with the researches of Dr. Ch. Ed. Guillaume, the present director of the Bureau, into the properties of invar, and was closely concerned with the early standardisation of the 24-metre Jäderin surveying wires, which are now almost universally employed in the measurement of geodesic base-lines. He was further interested, from his earliest days, in questions of electrical standardisation, and spent much time in determining the value of the standard ohm. This work, however, was not part of the regular programme of the Bureau, and the pressure of his other duties prevented him from devoting so much attention to it as he would have liked; but for a period the standard ohm produced by Benoit was the accepted type for precision measurements, and the value he obtained was very close to that accepted at the present time. He was still at work on this subject when failing health and eyesight caused him, in 1914, to tender to the Comité International his resignation of the directorship which he had held with so much distinction.

To appreciate the value of Benoît's work and his unsparing labour and painstaking attention to every detail making for precision of results, it is necessary to read the "Travaux et Mémoires" of the Bureau during the period of his direction. In appreciation of his services the Comité International, on his retirement, appointed him honorary director, and he was present in the autumn of 1921 at the sixth Conférence Générale des Poids et Mesures, showing all his old enthusiasm for the work which had filled his life. He had a most unassuming and charming personality, and those who had the privilege of knowing and collaborating with him will feel a very real and personal loss in his death. He was past president of the Société Française de Physique and correspondant of the Institut de France, of the Bureau de Longitudes, and of the Académie des Sciences, honorary fellow of the Physical Society of London and of the Société Française des Électriciens, and officer of the Legion of Honour.

J. E. S.

JOHN WANKLYN MCCONNEL.

A COMBINATION of business ability and legal training with real experience of agriculture as well as of textile engineering, directed by a passion for constructive organisation, brought the late Mr. J. W. McConnel to occupy an exceptional position as an exponent of industry in relation to science, and his death on May 25 at the age of sixty-seven is more than premature. His grandfather founded the firm of McConnel & Co., fine cotton spinners, whose mills are now the second largest in the world, in 1797, and Mr. McConnel was thus one of the aristocrats of the industry. The purchase by McConnels of the English patent rights of the Heilman Comber gave him, as a young man, an exceptional experience with the one new machine which the industry has evolved during the century; this experience influenced his outlook in later years, and seemed to render him much less convinced of finality than most cotton spinners, and hence more eager for the application of scientific methods. Incidentally, it may be mentioned that he was one of the first two students in the then new school of engineering at Cambridge. Thus he was led to advance a scheme for the formation of a special department in Manchester University at the British Association meeting of 1915; but, failing to secure a permanent endowment, he obtained the co-operation of the Fine Cotton Spinners' and Doublers' Association to undertake the proposed scientific work, which has since steadily developed into an experimental department of the combine with workshops and spinning mill as well as laboratories.

The original intention was merely in advance of public opinion, for only two years later Mr. McConnel became chairman of a provisional committee of the Department of Scientific and Industrial Research. He resigned the chairmanship, after two years' work, before the British Cotton Research Association was actually constituted, but not before he had laid the foundations of an immense organisation which embraces the whole industry, and aims at breaking down the watertight compartments into which a highly efficient but conservative industry had segregated itself. It is pleasant to recall the graceful acknowledgment of this "spade work" recently made by Mr. Kenneth Lee at a luncheon when H.R.H. the Duke of York formally opened the Shirley Institute, Mr. McConnel being present as a guest.

The thesis of essential community of interest between grower and spinner had found a strong supporter in Mr. McConnel. Travels to the West Indies, Egypt and the Sudan, supplemented by an active personal supervision of a very large cotton-growing plantation in Mississippi, and of his own estate in Ayrshire, placed him in an exceptional position as an authority on spinning who also knew a great deal at first hand about cotton-growing. Having first applied this experience in laying the broad foundations of the British Cotton Industry Research Association, he developed it further on the committees set up by the Board of Trade, his appendix to the Textile Committee's report leading to the formation of the Empire Cotton Growing Committee, and when the committee was transmuted into the Empire Cotton Growing Corporation under royal charter, Mr. McConnel became chairman of its council.

Mr. McConnel was most remarkable in an ability for learning new methods, subjects, and viewpoints which would have been unusual even in a much younger man. The work he initiated for the cotton industry was neither superficial nor conspicuous, but its effects will endure, and he will be remembered as one of those who thought for to-morrow as well as for to-day.

F. W. SANDERSON.

MR. FREDERICK WILLIAM SANDERSON, headmaster of Oundle School, whose tragic death occurred on Thursday, June 15, at the close of an address to the National Union of Scientific Workers on "The Duty and Service of Science in the New Era," made a deep and lasting impression upon scientific education in this country. He had just concluded his address, and Mr. H. G. Wells, who presided, had described him as the greatest headmaster that ever lived, when he slid from the chair in which he was sitting, and a few minutes later died from heart failure. Mr. Sanderson, who was born on May 13, 1857, was 11th wrangler at Cambridge in 1882, and assistant master at Dulwich College from 1885 to 1892, when he was appointed headmaster of Oundle School, Northants, which he transformed from a small and relatively unknown institution to a great and leading educational power. No Public School in the kingdom possesses such laboratories and workshops, and in none is it possible for a boy to be better prepared for worthy citizenship in a modern community. In all subjects Mr. Sanderson introduced methods of instruction which are both effective and stimulating. The practical method of teaching science is combined with lessons on the romance of the subject and points of contact with the action of Nature and the work of man in everyday life: library research is encouraged in connection with history and literature: English by reciting and acting an adapted play of Shakespeare's every term: languages by direct methods, and so on throughout the curriculum. Mr. Sanderson was not only an original thinker but also a tireless experimenter in educational methods, and his breadth of interest was so great that the classical and literary work at Oundle is as distinctive as that in science. The spirit of it all is that of education for service—creativeness rather than personal possession—and Mr. Sanderson's last words were a plea for this uplifting principle in every school. Oundle remains a noble monument to his high ideals and their successful achievement.

WE much regret to see the announcement of the death, on June 18, of Prof. J. C. Kapteyn, foreign member of the Royal Society and professor of astronomy and mechanics in the University of Groningen, Holland.

Current Topics and Events.

DIRE experience, in the form of aerial disasters, is emphasising the fact that the new form of locomotion possesses points of difficulty, and that the complexity of the problems presented is unparalleled in any of the older branches of transport. In delivering the annual lecture in memory of Wilbur Wright before the Royal Astronomical Society on June 15, Mr. Alec Ogilvie dealt with some aspects of the problem, and his address contains the following striking paragraph: "It is not my wish to exaggerate the importance to the world's knowledge of aeronautical research of the Wright brothers, but it is my desire to lay the strongest emphasis on the lesson to be learnt therefrom—namely, that the whole basis of aeronautical progress rests on genuine research in the laboratory, on the development of mathematical lines of attack, and on full scale research work in the field, and cannot possibly rest only or even mainly upon technical development." The lecturer said that the national effort put into aerial research was now far below the pre-war standard, and that the importance of fundamental research is not grasped by those in authority in this country. It may be recalled that the Royal Aeronautical Society, to which Mr. Ogilvie was speaking, has taken an active part in bringing the views of scientific aviation to the notice of the Air Ministry, and is the accepted representative body for that purpose. Moreover, during the later stages of the war, when aviation was taking a leading part in fighting operations, Mr. Ogilvie was responsible to the Air Board for its new designs of aeroplane, and this lends additional interest to his statement that "our rapid technical development during the war period, in which we as a nation overtook both friends and enemies after starting a long way behind, was mainly due to the solid research work which was done in the laboratories of this country between 1909 and 1914. It appears to me, however, that there is some danger that the real lessons of the past have not been understood and taken to heart." Mr. Ogilvie claimed for the Wright brothers a greater measure of praise for their demonstration of the firm structure of knowledge than for their superior skill and technique. The latter has hitherto been appreciated and the former neglected, but indications, still only straws, seem to point to a more even balance between research and technique in the immediate future of aviation.

THE Mount Everest expedition has made another new record in altitude. The *Times* announces that Messrs. Finch and Bruce with one Gurkha camped at 25,000 ft. for two nights and, employing oxygen, finally attained an altitude of 27,200 ft. This is 400 ft. above the record reached by Messrs. Mallory, Somervell, and Norton on May 21, and only 1800 ft. below the summit of Mount Everest. The *Times* also publishes a long despatch from General Bruce, giving details of the organisation of camps and transport on the Rongbuk glacier and Chang La (North Col). The route to the highest camp, at Chang La, was very trying, and unsettled weather added to the difficulties, but each camp was made self-complete with stores and equipment, the Chang La camp having food for ten British and a large number of porters, besides a full Alpine kit and the oxygen apparatus. It has been proved that up to 25,000 ft. a camp can be established without employing oxygen, and this gives considerable hope for the final assault on the summit. In the same despatch Mr. Mallory gives an account of the climb from Chang La camp to 26,000 ft. This altitude was reached without much more physical discomfort than

was experienced some 7000 ft. below, but one of the party, Maj. Morshead, was overcome and had to fall out. In such a case long rest at a lower altitude seems to be essential. The pace was very slow, but a greater height could possibly have been reached if the necessity for returning to the camp had not led Mr. Mallory to believe it wise to turn before the north-east shoulder was reached.

THE long drought of 1921 has been followed by excessive flowering of many kinds of trees and shrubs during the present spring, but in no instance has this been more noticeable than in the hawthorn, for both as a cultivated plant and as a wilding it has rarely been known to flower so freely. Dr. C. J. Bond, of Leicester, directs attention to this subject in a letter just received. In addition to its blossoming more freely than usual, hawthorn has been remarkable from the fact that a considerable number of plants have borne pink or pink-tinged flowers. This has given rise to speculation as to the reason for the sudden appearance of so many pink-flowered plants, and suggestions have been made that it may be due to the abnormal conditions of sunshine and drought obtaining last year and during the present flowering time, or to a process of evolution that is gradually taking place in the species. But pink-flowered hawthorns have not been uncommon in a wild state in the past, and it is doubtful whether the actual percentage of pink-flowered plants is any higher this year than in any previous year, but so many more plants than usual are flowering that they attract more attention. Pink and red flowered hawthorns have been grown in gardens for a very long period, and not infrequently they have been planted in parks, hedgerows, and on the outskirts of woods. Seed collectors in autumn are unlikely to distinguish between these and white-flowered trees, while birds are even less likely to discriminate. From such seeds, plants bearing white, pink, or pink-tinged flowers may be expected. These plants, used for field hedges, may 30 or 40 years later run wild and appear as trees, or seeds carried by birds and dropped in uncultivated ground may produce pink-flowered trees. While interesting, the appearance of pink-flowered hawthorns under wild or semi-wild conditions cannot be regarded as a new phenomenon or of great botanical importance, and it is unlikely that any marked natural change in the colour of the flowers throughout the species is in progress.

AN interesting discovery of a prehistoric village site is reported from Sidmouth. During the last year, workmen who have been employed in laying out the grounds of the residence of Mr. D. Chambers in Sidroad, have brought to light a number of objects, more than three hundred in all, and ranging in date from neolithic times to the eighteenth century. The finds include stone axes, arrow-heads, scrapers, flint knives and cores, a quantity of pottery, objects probably of Saxon and Norman date, and modern glass, of which one fragment is dated 1717. One object of flint, about one inch in diameter, is claimed to be a representation of the human face. Many of these objects were found in the course of removing old earthen banks, some of which may possibly have formed part of the original protective works of the site. The river and an adjacent brook provided an ample water-supply, while the site, which is well above the level of the river meadows, is situated within a quarter of a mile from the old Roman road from Exeter to Lyme Regis. The discovery is of particular interest in view of the evidence it affords of continuous occupation over such a considerable period of time. The objects discovered are now on exhibition in the house of the owners of the site and are available for the inspection of visitors, but ultimately a selection from them will be presented to the town.

THE Albert Medal of the Royal Society of Arts for 1922 has been awarded by the Council, with the approval of the president, H.R.H. The Duke of Connaught and Strathearn, to Sir Dugald Clerk, in recognition of his important contributions, both theoretical and practical, to the development of the internal combustion engine, which in its later forms has rendered aerial navigation possible, and is also so extensively employed in the motor car, in the submarine, and for many other purposes. The Albert medal was founded in 1863 as a memorial of the Prince Consort, who was president of the Society from 1843 to 1861, and is awarded annually "for distinguished merit in promoting Arts, Manufactures, and Commerce."

THE annual conversazione of the Institution of Civil Engineers will be held on Tuesday, June 27, at the Institution, at 8.30 P.M.

THE Jenner Medal of the Royal Society of Medicine has been awarded to Dr. J. C. McVail, and will be presented at the annual dinner of the Society on Thursday, July 6.

MR. J. H. NICHOLSON, assistant lecturer in education in the University of Bristol, has been elected to an Albert Kahn Travelling Fellowship. The value of the fellowship is 1000*l*.

BY invitation of the director of the Royal Horticultural Society's Gardens, Wisley, Ripley, Surrey, the annual field meeting of the Association of Economic Biologists will be held in the Gardens on Friday next, June 30.

THE annual general meeting of the Research Defence Society will be held at the house of the Medical Society of London, 11 Chandos Street, Cavendish Square, W.1, on Tuesday, June 27, at 3.30. The chair will be taken by the Rt. Hon. Viscount Knutsford, and a short address will be given by Sir Walter Fletcher on medical research and national life.

IN connection with the annual general meeting of the Eugenics Education Society a conference on "The Inheritance of Mental Qualities, Good and Bad," will be held at the Royal Society, Burlington House, on Tuesday, July 4, at 5.30. Among the speakers will be Dr. Tredgold, Dr. C. H. Bond, Dr. Bernard Hollander, and Mr. R. A. Fisher.

THE following officers and members of council of the Röntgen Society have been elected for the session 1922–1923: *President*: Sir Humphry Rolleston; *Vice-Presidents*: Sir W. H. Bragg, Sir Ernest Rutherford, and Dr. A. E. Barclay; *Hon. Treasurer*: Mr. Pearce; *Hon. Secretaries*: Dr. E. A. Owen and Mr. R. J. Reynolds; *Hon. Editor*: Dr. G. W. C. Kaye; *Council*: Mr. C. Andrews, Dr. G. B. Batten, Mr. A. E. Dean, Mr. K. Edgcumbe, Mr. N. S. Finzi, Dr. F. L. Hopwood, Dr. F. H. Johnson, Mr. C. E. S. Phillips, Prof. A. W. Porter, Prof. A. O. Rankine, Sir Archibald D. Reid, and Dr. R. W. A. Salmond.

REFERRING to a paragraph in NATURE of June 10, p. 755, Dr. Marie C. Stopes writes:—"May I correct the impression your paragraph creates that the Clinic and the *Birth Control News* are activities of the Malthusian League, as this is not the case? The Society for Constructive Birth Control and Racial Progress, with which the clinic and news are associated, is a distinct society with a different basis. The policy of the Clinic and the *Birth Control News* is that of *constructive* and scientific control, as distinct from what is commonly understood as Malthusianism."

WE have received from Messrs. C. F. Elwell, Ltd. (Craven House, Kingsway) a handsomely produced catalogue relating to apparatus for wireless communication. A readable introduction deals with the immensity of the field of wireless telegraphy and the superiority of the continuous wave over the spark system of transmission. The most interesting portion is that dealing with the Elwell arc equipment on the Poulsen system, such as the company has supplied to several well-known long-distance stations, including Horsea, Eiffel Tower, Lyons, Rome, and the initial station of the Imperial Chain at Leafield. This apparatus is listed up to 700 amp. in the arc. Interesting details are also given of steel and wooden lattice aerial towers, ship receiving sets, and various accessories.

Our Astronomical Column.

THE METEORS OF PONS-WINNECKE'S COMET.—Mr. W. F. Denning writes that he regards it as highly probable there may occur a meteoric shower on about June 28. It will be a return of the display which he witnessed on June 28, 1916. If the meteors of this stream are connected with the comet of Pons-Winnecke, they will have a period approximating six years, and as the particles appear to be distributed abundantly along a lengthy section of the orbit, a repetition of the phenomenon of 1916 may be expected. It is true that the cometary meteors were not seen at many stations last year, although the conditions appeared promising, but in Japan a considerable number seem to have been recorded. In any event it is desirable carefully to watch the heavens, at the end of June, for further evidence of this interesting display. There will be no moonlight, and the radiant point in Quadrans or Draco will be favourably placed in the earlier hours of the night.

THE SEARCH FOR NEW STARS.—The period of the year is now approaching when the Milky Way will be very favourably placed for observation in northern latitudes, especially towards the end of June, and in July. The constellations Cygnus, Aquila, Ophiuchus, and Scorpio have been fruitful in Novæ in past years, and they offer the prospect of further discoveries. When the moon is not bright the sky in the regions indicated should be scanned carefully for new objects. The best time to conduct the work will be near midnight, when the summer twilight will not seriously interfere.

An observer who is not familiar with a large number of the naked-eye stars, should compare the heavens with a star atlas, and this method, often repeated, will soon enable him to dispense with the atlas. Certain new stars are very quick in their rise to brilliancy, and a vast difference in their magnitude often occurs in a few hours, so that it is really essential to repeat the search several times in the course of a night. Wherever the galaxy runs the observer's eyes should diligently pursue the quest, and other quarters of the sky should occasionally receive attention.

Though twelve new stars visible to the naked eye burst into view between 1848 and 1921, not one appears to have been recognised during the previous 158 years; but this was probably due, not so much to the dearth of such objects, as to the want of capable observers.

COLOURS OF BINARY STARS.—The giant and dwarf theory of star-development gave a solution to an astronomical enigma of long standing. This was the frequency with which the fainter component of a binary tends to blue, while the brighter component is red or orange. On the old view this implied that the component was of earlier type than the bright star, and hence had developed more slowly. Some suggested, as a way of escape, that the blue of these stars might possibly not correspond with that associated with spectral type A or B. It was, however, found possible to obtain spectrograms of some of these blue components, which did not indicate that they differed from other blue stars. As soon as the giant and dwarf theory was mooted, it became clear that for giant stars the blue stage was in fact later than the red or yellow one.

Mr. Peter Doig examines the question from this point of view in Mon. Not. R.A.S. of April, and finds that it gives much the same line of demarcation between the giant and dwarf binaries as that given by the absolute magnitudes, based on all available parallaxes, including the spectroscopic ones. He gives 33 pairs in which the stars are giants, and 75 in which both are dwarfs. The former list includes Polaris, Regulus, Antares, β Cygni, ξ Bootis, etc.; the latter includes Castor and α Centauri. Mr. Doig notes that in some cases of great difference of mass the companion might have become a dwarf of a redder type than the primary, while the latter was still a giant. He then ventures to extend the principle to give estimated parallaxes for some systems not on the list. For example, α Librae is given as a dwarf, with parallax $0{\cdot}045''$; the parallax of Praesepe is estimated as $0{\cdot}010''$. The paper makes an appeal for the substitution of other terms for "early" and "late" as applied to spectral types, which are misleading in the case of giants. Prof. Turner suggested the terms "hotter" and "cooler" as preferable.

Research Items.

FRAZER MEMORIAL LECTURES.—Some admirers of Sir James Frazer's work in social anthropology have contributed to a fund for the establishment of an annual lecture at Oxford. The first lecture in the course was recently delivered by Dr. E. Sidney Hartland, who naturally selected as his study a subject which he has made his own, "The Evolution of Kinship," based upon the important monograph by Edwin W. Smith and the late Andrew M. Dale on "The Ila-speaking Peoples of Northern Rhodesia." The Ba-ila, or Ila people, inhabit the very centre of the continent, on the banks of the Kafue, a tributary of the Zambesi, being descendants of more than one stream of Bantu immigrants from the north and north-east, coming probably by different routes and at different times. The social organisation of this primitive and hitherto little-known community has been skilfully investigated by Dr. Hartland. Like all Bantu tribes, their civilisation is based on the matrilinear clan, the family being a newcomer into the social field, which is struggling with the clan for influence. Its development into a patrilinear institution is plausibly accounted for by the rule that on marriage a wife goes to her husband's dwelling and makes her home there: he does not come to that of her kindred. Thus the developmental sequence, as among the Australian tribes, is from mother to father right. If succeeding contributors to this foundation maintain the high level of Dr. Hartland's inaugural lecture, the Frazer Memorial Lecture marks an important extension of the study of social anthropology in this country.

AN INSECT DESTRUCTIVE TO FLAX.— In the Scientific Proceedings of the Royal Dublin Society, vol. xvi., April 1922, Mr. J. G. Rhynehart contributes an interesting and well-illustrated paper on the flax flea-beetle (*Longitarsus parvulus* Payk.). This species is a serious enemy of flax and one responsible for considerable loss to growers of the crop in Ireland. It is commonly found throughout Ulster, and of recent years has become a pest in flax-growing districts in Co. Cork. The adult beetle kills many of the seedlings by devouring the cotyledons and growing-point of the flax, but will also eat clovers, grasses, and wild species of flax. The larvæ bore into and feed on the roots of the flax plants, but do not appear to cause any appreciable hindrance to growth. Preventive measures consist of the production of strong, vigorous-growing brairds by the employment of suitable cultivation, seed, and manure; in the destruction or removal of all material likely to afford means of hibernation for the adult beetle; and in the stimulation of attacked seedlings by the application of a light dressing of nitrate of soda. Preliminary experiments indicate the possibility of the use of Bordeaux mixture as a deterrent.

NEW FOSSIL SEA COW FROM FLORIDA.—The hinder part of the right maxillary of a species of Metaxytherium, from the phosphate beds of Mulberry, Florida, is described and figured by Mr. O. P. Hay under the trivial name of *M. floridanum* (Proc. U.S. Nat. Mus., vol. lxi.). Its exact geological horizon is uncertain: it belonged probably to the Upper Miocene or Lower Pliocene, while European species belong to the Miocene or in part to the Oligocene.

PALÆONTOLOGY OF THE BURMA OILFIELDS.—For some years Mr. E. Vredenburg has been accumulating data regarding the marine fauna of Tertiary age in Burma, and the large quantity of material collected by officers of the Geological Survey of India, as well as by the geologists of the principal oil companies, now permits of a marked advance on the results as they were left by Dr. F. Noetling in 1897. A general revision of the Tertiary formations of the Burma oilfields region was published by Mr. Vredenburg last year (Records Geol. Surv. Ind., vol. li., Part 3). This has been followed by a series of papers issued in anticipation of complete monographs on the Tertiary molluscan fauna, which will be considerably delayed for the reproduction of the required illustrations. The papers issued so far cover the four gastropod families of Terebridæ (vol. li., Part 4), Pleurotomidæ, Conidæ, and Cancellariidæ (vol. liii., Part 2). The completion of this work, if not unduly delayed, should be of great value to oil geologists in their attempts in Burma to identify in newly explored areas the known horizons of the established oilfields.

CHANGES OF CLIMATE IN AUSTRALASIA.—Mr. R. Speight, as secretary of the Cainozoic Climate Committee, has drawn up a valuable report for the Australasian Association for the Advancement of Science (A. J. Mullett, Government Printer, Melbourne). Evidence is adduced from the fossil floras from W. Australia to New Zealand to show that a general warm temperature prevailed in mid-Cainozoic times. Extensive estuarine deposits with shells, and the occurrence of Diprotodon, point to a high rainfall in the Upper Pliocene and early Pleistocene epochs, in what are now arid, or almost arid, regions in Australia. Desiccation followed, extending in the south and centre to the present day. Agreement is expressed with Prof. T. G. Taylor's conclusion that "the climatic belts are moving poleward from the equator. The desert region is encroaching on the southern coasts of the Continent. The northern littoral is getting wetter." The laterites of the northern territory and of northern Queensland are referred to greater aridity here in early Pleistocene times. The cooling that gave rise to a glacial stage, at any rate in New Zealand, may have been as much as 5° C. (9° F.) in southern Australia, and occurred before the aridity set in. The question of a general southern glaciation is, however, not touched on in the report.

NEW SENSITISER FOR GREEN LIGHT.—Dr. W. H. Mills and Sir William Pope of Cambridge (Journal of the Chemical Society, May, p. 946) have discovered a new sensitiser for photographic plates, which they state to be the most powerful sensitiser for green light yet known. It is especially noteworthy also because the gap in the bluish green, which appears almost always when using sensitisers for this region of the spectrum, does not occur with it. The substance, 2-*p*-dimethylaminostyrylpyridine methiodide, is produced as bright red prisms when condensation is caused to take place between *p*-dimethylaminobenzaldehyde and 2-methylpyridine methiodide with the aid of piperidine. Gelatino-bromide plates, after bathing in an aqueous solution containing one part of the dyestuff in thirty or forty thousand parts, show almost uniform sensitiveness to light of all wave-lengths from the blue to about λ 5600, at which point the sensitiveness rapidly declines and ends at about λ 6200.

Carnegie Institution of Washington.[1]

THE year 1921 marks the completion of the twentieth year of organised research conducted by the Carnegie Institution. The original aim of the Founder was to give encouragement and support to investigations or to constructive thought in any department of science, literature, or art, and it is gratifying to record the fact that at the end of this second decade, the function of research as an activity indispensable to civilisation and as a necessary prerequisite of progress, seems to have come into fuller recognition than at any previous time in history. Industrial and government agencies, as well as academic interests, have given to fundamental investigation a high place in the list of elements essential for advance. To-day one may say with confidence that no investment of funds or of personal effort can find a work of greater dignity and worth, or one which offers a future giving clearer evidence of abundant and continuing reward, than is open in the field of research.

The work of the Institution touches in one way or another upon nearly all of the principal fields of research, and the investigations have been very fruitful. They have been not merely contributions to knowledge, but they are also the basis for much research of application which goes immediately into human use. It is not necessary in a preliminary statement to do more than direct attention to some of the most significant results which have signalised certain phases of the work of the Institution in the past year.

It is doubtful whether any recent discovery in the physical sciences has attracted wider interest or has contributed more to the ultimate possibilities of astronomical and physical science than the measurement of diameter of a fixed star carried out at Mount Wilson Observatory three days after the annual meeting of the Institution last year. This long-desired result was made possible by many years of development of plant and technique, together with the extraordinary skill of Dr. A. A. Michelson and his associates and the clear vision of Dr. G. E. Hale in bringing together all of the elements required for this particular task. Measurement of the diameter of the star Betelgeuse once accomplished, the dimensions of other stars followed quickly. More recently, by a refinement of the original method, Dr. Michelson has opened the way for corresponding observations on a group of stars which seemed to be entirely out of range in the first use of the interferometer on the 100-inch telescope. The results already achieved give confirmation of much important work done by other astronomers and furnish a new starting-point for a great variety of investigations concerning the nature of the universe. In consideration of the critical problems involved, provision has been made for securing assistance and co-operation of other investigators, and Dr. H. N. Russell, of Princeton University, who has added much to our knowledge of the evolution of the stars, is now associated with Dr. Michelson and others in helping to solve the special problems to which Mount Wilson Observatory has given attention.

A significant event in the operations of the Institution is the completion within this year of a survey of the seas of the world by the non-magnetic ship *Carnegie*. Launched in 1909, this unique vessel has voyaged nearly 300,000 miles, covering the principal areas of the great oceans and securing data on magnetic conditions previously unavailable, which, with those obtained by concurrent studies on land, give a map of magnetic variations not hitherto possible. With the completion of the year's cruise by the *Carnegie*, and the summing up of its results, attention may be directed more particularly to land observations, to critical studies of terrestrial and atmospheric electricity, to experimental studies bearing upon the nature of magnetism, and to the assembly and interpretation of the great mass of data made available from all sources through many years of field work.

Beginning with the year 1921, the Department of Experimental Evolution and the Eugenics Record Office have come to function as an administrative unit known as the Department of Genetics. By this change, the biological studies of inheritance, based upon investigation of many groups of plants and animals, are brought to bear more directly on studies of human genetics conducted through the Eugenics Record Office. Important as knowledge of heredity is in its application to the development of the animals and plants which contribute to our needs, there is no group of questions more significant in the complicated organisation of human society than those concerning the meaning and the possibility of direction or control of inheritance in man. Without full understanding of the biological factors concerned, it might appear that intelligence and social organisation have brought relatively large opportunity for degeneration. On the other hand, adequate understanding of the principles governing the course of descent may give to mankind opportunity for more rapid and more advantageous development than has been known in the past lines of evolution of other organisms.

During the past year a modest chemical laboratory has been erected for the Department of Botanical Research at Carmel, California. This department has carried its work farther into the field of physical and chemical research in the effort to secure more information concerning the basis of plant activities. The new laboratory offers improved opportunity for fundamental work on photo-synthesis or the chemistry of compounds arising under the influence of light, and it is hoped that with present facilities a nearer approach to the solution of this difficult but fundamental problem in the physiology of plants may be obtained.

An important project in the purely humanistic field is that concerning the ancient Maya civilisation of Central America. The expedition of 1921, led into this region by Dr. S. G. Morley, has secured most significant new material by the study of the ancient monuments and the excavation of building sites. The story of this people contributes much that may become critical or determinative in the interpretation of early American history; the great bulk of this record still remains unread. In the past year the Institution has had the benefit of effective co-operation in this work by Mr. William Gates, whose study of both the modern and the ancient Maya language involves lines of investigation which should relate themselves closely to the archæological studies.

The more noteworthy of the allotments made by the Executive Committee during the past year were as follows: 14,000*l.* for the Department of Botanical Research, 25,000*l.* for the Department of Genetics, 28,000*l.* for the Geophysical Laboratory, 42,000*l.* for the Mount Wilson Observatory, and 46,000*l.* for the Department of Terrestrial Magnetism.

In addition, there were minor grants aggregating 30,000*l.*, and 20,000*l.* was allotted for the production of publications. The total allocations amounted to more than 250,000*l.*

[1] Extracts from the Report of the President of the Carnegie Institution of Washington, Year-book No. 20, 1921.

Since the foundation of the Institution in 1902 there has been distributed, chiefly by gifts to libraries and to authors, but to a noteworthy extent also by sales, a total of no less than 226,039 volumes of publications of the Institution. During the past year the publication of 23 volumes has been authorised by the Executive Committee at an aggregate estimated cost of 12,000*l.*, and 18 volumes, with an aggregate of 4068 octavo and 1398 quarto pages have been issued. Twenty additional volumes are now in press.

Melanesian Witchcraft.

AT a meeting of the Royal Anthropological Institute on Tuesday, May 23, Dr. B. Malinowski read a paper on Melanesian witchcraft. The natives of the Coral Archipelagoes surrounding New Guinea, where Dr. Malinowski carried out his researches, have no idea of natural death or disease. If undisturbed by sorcery, a man would, they believe, live in perpetual good health to an old age, in fact there is no reason why he should ever die.

When a sorcerer wishes to destroy a man, either as an act of personal hate or professionally for a payment, he first administers a small dose of black magic and produces a slight disorder. A spell in which the victim's name is mentioned is chanted over his house or garden, or into some leaves which are buried near his doorstep. The man sickens and is made more susceptible to further evil magic, which is now made stronger by the application of a more dangerous spell, and the pernicious substance must be administered by mouth or else burnt in the victim's hut. At this stage the patient takes all sorts of precautions; his house is guarded by relatives, his food is under control and, last though not least, he engages the services of another professional man—a sorcerer is always also a healer—who tries to undo by magical means all the evil done by his colleague. The sorcerer is most dreaded at night when he prowls round the victim's house, surrounded by night birds, his assistants, and tries to enter the hut and to burn the deadly substance.

If he succeeds, the patient may die, provided the good magic has not proved more effective than the evil. If he fails, the sorcerer may have recourse to the final rite of pointing the bone. A regular witch's cauldron is prepared and boiled somewhere in the jungle, and into its seething contents the sorcerer chants a most deadly spell, uttering the victim's name. Then he dips into the mess a pointed bone, a stingaree spine, or a short wooden dagger. Afterwards he steals to the village and tries to get sight of the victim without being seen himself. Pointing the dagger towards the man he jerks and twists it in the air, muttering the final incantation. The man to whom this is done will invariably die, unless a more effective magic has been used for his protection.

The sorcerer firmly believes in the powers of his black art. When he undertakes professionally to conduct a case, whether of killing or curing, he will carry out the various rites scrupulously, often risking his life in the attempt to kill by magic, for, if caught *in flagrante delicto*, he would be mercilessly speared.

It has to be realised that sorcery is almost invariably used to avenge some real injury or to punish some one who has broken the tribal law. The victim feels the weight of public opinion against him and this enhances greatly his natural fear of magic. It is important also to realise that black magic is generally used in carrying out the decrees of tribal law and usage, and that it is mainly at the disposal of the chief, the man of rank, and the man of wealth. It thus supplies savage society with the wholesome, though undoubtedly unpleasant element of fear, without which no social stability or order can exist in a primitive community. It is always a conservative force, which ranges itself on the side of existing order, authority, law, and custom. It is most unfortunate, therefore, that whenever European civilisation comes in contact with savages, the first thing done is to destroy, or at least undermine, the power of the black magician. It is one of the many cases where a mistaken zeal for giving savages that for which they are not yet ripe results in the disruption of their own social order and in paralysing their own powers, without the substitution of any effective means of control.

The late Dr. Rivers, in opening the discussion which followed the reading of the paper, referred to the value of Dr. Malinowski's investigations in indicating in particular the place taken by sorcery in the social complex as a whole. When examined in this relation, the resemblance which the sorcery of the Trobriands offers to the sorcery of other peoples as, for example, in the Western Solomon Islands, is merely superficial. Sir James Frazer pointed out the parallelism in the development of the arts and of witchcraft in the Trobriands, and indicated further that the theory which underlies this system of sorcery is mechanical in that the spirit acts upon, but did not enter into, the body.

New Buildings of University College, Nottingham.

THE foundation stone of the new buildings of University College, Nottingham, was laid on Wednesday, June 14, by Lord Haldane, in the presence of a large company from all parts of the East Midlands. The site is situated at the highest point of the Highfields estate, being about 2½ miles distant from the centre of the city. The present proposals include the central building, which provides accommodation for the faculties of arts and economics and also for the administrative offices. The library adjoins. There is also provided a block for the departments of chemistry and physics with room for extensions. The departments of biology and geology will be temporarily accommodated in the central building. The departments of engineering, mining, technology, and the evening work of the College will continue to be carried on in the present buildings in Shakespeare Street.

The new buildings at Highfields have been designed on the unit system in such a way that future development of the University is rendered possible. Provision is thus made for the ultimate transference of all departments to the new site. The erection of the new buildings has been made possible by the great generosity of Sir Jesse Boot. About two years ago he gave to the College the sum of 50,000*l.*, of which 20,000*l.* was to be devoted to the endowment of the chair of chemistry and 30,000*l.* to the building fund. He has now added a further sum of 120,000*l.* towards the latter purpose. At the ceremony on June 14, Lord Haldane announced that Sir Jesse Boot had sent a further cheque for 10,000*l.*, and that an anonymous donor had forwarded a cheque for 100,000*l.* in aid of the movement. These two cheques were put by Lord Haldane in the hands of the chairman of the University College. With this

quarter of a million it will be possible to provide the buildings necessary to allow of the removal of the purely academic side of the University College from its present site, and also to provide the administrative accommodation which will be necessary for the proposed University if and when its charter is granted. The University College, by the terms of the draft charter to be presented to the Privy Council, will form the nucleus of the new institution, to be reinforced from time to time by the association of other colleges in the province as they are approved by the Board of Education. Hence it was appropriate for the architect of the new buildings, Mr. Morley Horder, to describe his drawings in the Royal Academy of this year as of the East Midland University.

The buildings will be of sober classical style in the English tradition of Wren. They will be grouped in a range of quadrangles rising from a lake, some twelve acres in extent, with a terraced garden in front. As the railway passenger approaches by the Midland line from Trent, the white Portland elevations of the various buildings will be seen on high ground to the left. Owing to the conformation of the site a view is obtained from the front of the University over the valley of the Trent.

The Highfields Park which surrounds the University buildings affords opportunities for such extensions as the future may demand. Beyond the ample provision thus made, extending to many acres, the large park, by the noble generosity of Sir Jesse Boot, is dedicated to the use of his fellow-citizens. On the southern side of the lake a wide boulevard, containing alternate roads and avenues of trees, affords an approach to the city from the west, and incidentally a means of access to the University buildings. From this boulevard there will open playing-fields, some of which will be allotted to the University. The amenities, therefore, of the city and the University will be combined in a manner which is advantageous to both. The laying out of the boulevard, the lake, and the park will involve a cost of some 200,000*l.*, which again is a gift from Sir Jesse Boot.

The imaginative construction of the whole imposing scheme is peculiarly that of the donor, and his especially is the credit in this respect. There are not many persons who have entered completely into his idea, and it is characteristic of his point of view that he insists that the first part of the buildings to be erected must include the fine terraced garden which shall unite the University buildings with the lake. This garden involves the fine stone retaining walls which are necessary upon the sloping ground. Lord Haldane spoke effectively of the ideal of a civic university, and it thus appears that it will be materialised through a conception which involves, not only the relation of the university to the city, but of the city to the university. Such a conception has formed itself for the first time in the mind of a citizen.

Rothamsted Experimental Station.

The Society for Extending the Rothamsted Experiments on Agricultural Science held its annual meeting at the Rothamsted Experimental Station, Harpenden, on Wednesday, June 14, when some 80 members of the Society and guests were present.

The morning was occupied in the inspection of some of the experimental fields, which were demonstrated by members of the staff. After luncheon the meeting was addressed by Lord Bledisloe, who presided in the absence of the Duke of Devonshire. Lord Bledisloe described the important function fulfilled by the Society for Extending the Rothamsted Experiments in assisting the station to pursue its investigations in agricultural science. He mentioned that it was hoped with the aid of Government grants to begin the construction of new laboratories at Rothamsted for the study of diseases and pests of agricultural crops, and to make other much-needed additions to the station. As the Government grant is conditional upon the station itself raising a certain sum by private donations, the Society hopes to collect 5376*l.* during the current year for this purpose. Lord Bledisloe concluded by voicing the congratulations of the meeting to the director, Sir John Russell, on the honour of knighthood recently conferred upon him in recognition of his work in agricultural science.

Sir John Russell then gave a brief account of the problems under investigation in the laboratories, after which the Minister of Agriculture, Sir A. Griffith-Boscawen, in a short speech, said that the policy of the Government was to make provision for, and to encourage, agricultural education and research as the safest and best means of helping British agriculture. He added that in this policy he had the support of all shades of agricultural opinion, and referred to the general approval of the recent grant of 1,000,000*l.* for education and research which was made when the Corn Production Act was repealed. Sir Daniel Hall, the Chief Scientific Adviser to the Ministry of Agriculture and a former director of Rothamsted, also spoke, and pointed out the great value of the experimental fields to Rothamsted, in that they focussed attention upon problems which had both scientific and practical interest.

Mr. Shepperson of the National Farmers' Union, and Mr. George Dallas of the Workers' Union, also expressed on behalf of their respective organisations their support of the policy outlined by the Minister of Agriculture.

In the afternoon the visitors inspected the laboratories and discussed with the staff some of the investigations in progress. Special attention was given to the work of the entomological and mycological laboratories, which at present is being conducted in unsuitable and overcrowded quarters. It is hoped that the effort of the Society for Extending the Rothamsted Experiments will enable adequate accommodation to be provided for this work in the near future.

University and Educational Intelligence.

Cambridge.—Mr. F. C. Bartlett, St. John's College, has been appointed reader in experimental psychology and director of the Psychological Laboratory. Mr. H. A. Cox has been appointed Gurney University lecturer in forestry. Mr. G. S. Carter, Gonville and Caius College, has been elected to a research studentship at Naples and nominated to use the University table there. Honorary degrees are to be conferred on ex-President Taft, Chief-Justice of the Supreme Court of the United States of America, and upon Mr. H. Stone, University lecturer in forestry.

The following elections and awards are announced: to a Harkness scholarship in geology, H. Hemmings, St. John's College; to Frank Smart prizes in botany and zoology, J. Barker, Trinity College, and C. F. A. Pantin, Christ's College, respectively; to the Wiltshire prize in geology, W. D. West, St. John's College.

St. Andrews.—At a meeting of the University on June 9, a letter was read from Prof. A. S. Butler resigning the chair of natural philosophy as at the end of September. It was agreed to announce the

vacancy of the chair and invite applications. The appointment of a professor of education to the chair vacant owing to the death of Prof. John Edgar has been deferred, and applications are invited for a lectureship in education with a salary of 500*l.* a year. The following appointments have been made: Mr. F. Whyte, to be lecturer in engineering in University College, Dundee; Mr. M. McGibbon, to be demonstrator in botany, and Miss J. M. Reid to be demonstrator in zoology at St. Andrews.

THE United States Bureau of Education has issued as Bulletin No. 30, 1920, a supplement for 1918 and 1919 to the Digest of State laws relating to public education which it published in 1915. It shows considerable activity on the part of the State Legislatures, the output of the two years being about 3000 enactments without counting those of local application or ordinary appropriations. Among those of special interest are the provisions for establishing continuation schools. Seventeen States passed laws making attendance compulsory, in most cases until the age of 18, and for not less than 8 hours a week. Numerous laws were passed to promote "Americanization" through adult education in the English language, civics, etc. Connecticut, for instance, established a State Department of Americanization under a Director; New York required the State University to prepare courses of instruction in patriotism and citizenship and provided for enforcing the attendance of children over 8 years of age; Texas provided for at least ten minutes instruction each day in intelligent patriotism, and required school boards to provide a flag for each school building; S. Dakota required instruction in patriotism in all educational institutions, both public and private. Five States passed acts providing for military training in schools, one (New York) requiring such training not exceeding three hours a week for boys between 16 and 19. Illinois passed a law prohibiting fraternities, sororities, and secret societies in schools.

IN Bulletin No. 8, 1921, of the United States Bureau of Education, Mr. W. J. Osburn of the Department of Education of the State of Wisconsin has brought together a large number of extracts from reports made in the course of the past seventy years by English, French, and German observers. His comments are characterised by the United States Commissioner of Education as fair and helpful interpretation. While the object of the treatise is to extract from the work of the critics its maximum value for Americans, it is of great interest to educationists generally and provides most useful safeguards for those who in other lands are endeavouring to obtain inspiration and guidance from recent developments and experiences in American institutions. Most conspicuous among the criticisms dealt with are, naturally, those contained in the report of the Mosely Education Commission which was sent from England with instructions to find out to what extent American commercial prosperity has been due to their educational system. Many of the criticisms are by French university exchange professors; German critics have, in general, it appears, shown a bias in favour of autocratic methods and a consequent lack of understanding and sympathy. While satisfied that American achievements and tendencies compare, on the whole, favourably with those of other countries, Mr. Osburn directs attention to several serious shortcomings. He says, for instance, that conditions in the teaching profession leave much to be desired as regards salaries, security of tenure, and pensions, although the social standing of the teacher is good, while the annual output of teacher training institutions is less than one-fourth of what it should be.

Calendar of Industrial Pioneers.

June 25, 1879. Sir William Fothergill Cooke died.—While a student of anatomy and physiology at Heidelberg, Cooke in 1836 had his attention directed to the electric telegraph, and in 1837, on his return to England, he became a partner with Wheatstone. Joint patents were taken out in 1837 and 1838 for instruments with five and two needles, and in 1845 the single needle instrument was produced. After that the telegraph was speedily adopted on all the railway lines of the country. The first commercial telegraph of Cooke and Wheatstone was erected in 1837 on the London and North Western Railway between Euston and Chalk Farm.

June 26, 1827. Samuel Crompton died.—Employed in a cotton mill in Bolton, where he was born in 1753, Crompton devoted himself to the improvement of cotton machines. After five years' work, by combining the principle of Arkwright's rollers and Hargreaves' spinning jenny, he was able to produce, by means of his "mule," a yarn of hitherto unexampled fineness. Too poor to obtain a patent he remained comparatively poor, but in 1812 the merits of his invention were recognised by Parliament granting him a sum of 5000*l.*

June 26, 1810. Joseph Michel Montgolfier died.—The elder of the brothers, to whom is due the invention of the hot-air balloon, Montgolfier was born at Annonay in 1740, and became, like his father, a paper manufacturer. His first experiments with balloons were made at Avignon in 1782, and on June 5, 1783, Michel Montgolfier and his brother, Étienne, made the first public experiment in Annonay, where a century later a monument was erected to them. The use of hydrogen in balloons was due to the physicist, Charles.

June 28, 1817. George John Singer died.—The inventor of the gold-leaf electrometer, Singer in early life was a maker of artificial flowers. Given to private study he wrote on electricity and electro-chemistry, made improvements in electrical apparatus, and at his premises in Princes Street, Cavendish Square, gave lectures which were attended by Faraday and Francis Ronalds. He died of consumption at the age of 31.

June 28, 1915. Charles Ernest Paolo Della Diana Spagnoletti died.—For thirty-seven years—from 1855 to 1892—Spagnoletti was chief electrician and telegraph engineer to the Great Western Railway, and in 1885 served as President of the Society of Telegraph Engineers, now the Institution of Electrical Engineers. He brought out numerous electrical appliances for signalling, recording, and controlling, and was the inventor of a dynamo.

June 29, 1890. Alexander Parkes died.—Apprenticed to a Birmingham brassfounder, Parkes afterwards worked for Elkington and, during a period of forty-six years, took out some sixty patents relating to electroplating and other processes. He discovered the method of using zinc for the desilverisation of lead, and about 1855 invented the material now known as celluloid.

June 30, 1893. Jean Daniel Colladon died.—Of Huguenot descent, Colladon was born in Geneva on December 15, 1802. With the mathematician, Sturm—with whom he made experiments on the velocity of sound in the waters of Lake Geneva—he went to Paris and studied under Ampère and Fourier. Returning to his native city, he became a professor in the Geneva Academy and engineer to the Geneva Gas Co. He lectured on the steam engine, brought out a dynamometer, experimented on hydraulics, and was a pioneer in the use of compressed air for the transmission of power.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, June 1.—Sir Charles Sherrington, president, in the chair.—T. H. **Morgan**: The mechanism of heredity (Croonian lecture). The changes taking place when the germ-cells ripen are such that, granting the hereditary elements are carried by the chromosomes, the changes can serve as a mechanism, furnishing an explanation of the principles of heredity discovered by Mendel. In the course of the ripening of the germ-cells, irregularities occur at times in the distribution of the chromosomes, which can be followed in successive generations. The departures from the ordinary course of inheritance that are there shown, are found to be *exactly* related to the new distributions of the chromosomes. The facts furnish convincing testimony that the Mendelian characters are carried by the chromosomes. By the aid of the phenomenon known as "crossing-over" it is possible to determine that the hereditary elements lie in a single line in each chromosome. It is even possible to form a rough estimate of the upper limits of size of these elements, although at present such estimates are necessarily very crude, and are interesting only as the first attempt to determine the size of the "gene."

Geological Society, May 24.—Prof. A. C. Seward, president, in the chair.—A. C. **Seward**: Geological notes on western Greenland. Many localities were visited on the northern and north-eastern coasts of Disco Island, on the coast of Nugsuak Peninsula, also Hare Island, Upernivik Island, Ritenbenk, Sarkak, and Jakobshavn. Greenland is nearly 1700 miles long, with an average breadth of about 600 miles; approximately a hundred glaciers from the inland ice reach the sea, the largest of which, Humboldt Glacier, ends in a cliff 60 miles broad. Various forms of icebergs were seen. An account of the characteristic types of vegetation and the physical and geological features of Greenland was followed by a more detailed description of the Cretaceous and Tertiary sedimentary series of Disco Island and the Nugsuak Peninsula, and of the overlying and protecting basalts which in some places rest directly upon the old Archæan land-surface, to the exclusion of the sedimentary series. Most of the sedimentary rocks are freshwater in origin and there is evidence of recent sinking of parts of the western coast.

Linnean Society, June 1.—Dr. A. Smith Woodward, president, in the chair.—A. C. **Seward**: A study in contrasts: The past and present distribution of certain ferns (Hooker lecture). Ferns spread by vegetative means, and the lightness and resistant nature of their spores make them very successful as colonisers and emigrants. When Treub visited Krakatau three years after its violent volcanic eruption, he found eleven species of ferns as pioneers of the new flora. As a class, ferns are cosmopolitan, though certain of them are strictly limited in their range and highly sensitive to the influence of physical or climatic conditions, *e.g.* the Bracken, *Cystopteris fragilis*, and *Polystichum Lonchitis*. The apparent identity of living with dead plants gives reality to Hooker's idea expressed in one of his letters: "Geology gives no evidence of a progression in plants. I do not say that this is a proof of there *never* having been a progression—that is quite a different matter—but the fact that there is less structural difference between the recognisable representatives of Conifers, Cycadeæ, Lycopodiaceæ, etc., and Dicotyledons of the chalk and those of the present day, than between the animals of those periods and their living representatives, appears to me a very remarkable fact." The unfolding of plant-life through successive stages of earth-history shows a series of outbursts of energy; the records of one period tell us nothing, while those of the next reveal a fresh type of vegetation or, it may be, a single genus in possession of widely scattered regions of the world. The beginnings are always hidden from us. Between the Mesozoic and the Palæozoic records there appears to be a wide gulf. The difficulty of making direct contact between the age of pteridosperms and the succeeding age of ferns may be due to the difficulty of determining whether a Palæozoic fern-like frond should be classed as a pteridosperm or a true fern. In the latter part of the Triassic period we seem to pass suddenly to a new phase of plant evolution which may be intimately associated with some far-reaching event in the physical history of the earth's crust. Possibly crustal foldings in the latter part of the Palæozoic era, and the prevalence of desert or semi-arid conditions over wide regions during a part of the Triassic period, were vital factors influencing the progress of plant development. The rocks accessible cannot give all the clues sought; parts of old continents remain but others are beyond our reach.

The Optical Society, June 8.—Sir Frank Dyson, president, in the chair.—J. **Guild**: Angle comparators of high precision for the goniometry of prisms. The method of substitution is utilised. Measurements accurate to $1''$-$2''$ can readily be made, and with a more elaborate arrangement an accuracy of about $0 \cdot 1''$ is possible. For the latter, minute variations in the direction of a beam of light emerging from a collimator, caused by placing near the focal plane of the latter a "variable prism" of simple design, are measured.—T. **Smith**: The changes in aberrations when the object and stop are moved. If the aberrations of any centred optical system are known, both for an object which intersects all rays transmitted by the system and for the centre of the effective stop, the position in the image space of the emergent portion of a given incident ray is known, and the aberrations in the image of any other object for any stop position can be expressed in terms of those for the first object. The relations in the second case are expressed in terms of the first when the objects are planes normal to the axis of symmetry.—T. **Smith**: The classification of optical instruments. Five classes are proposed, based upon the separation of the four Gaussian constants into two groups according to their signs. This classification cannot be modified by the addition to the system of inverting prisms and the like, and the properties usually associated with the sign of the lens depend upon its class according to the new system. Each class may have systems of positive or of negative power.—T. **Smith** and L. M. **Gillman**: Note on achromatism with one glass. Systems composed of thin lenses of the same kind of glass, and achromatised by selecting suitable positions for the components, are members of the class (AD) (BC), so that if the object is real the image is virtual. Apochromatic systems constructed from normal achromatic lenses belong to the same class. The aberrations for systems constructed of a single glass, but belonging to other classes, are of considerable magnitude.—H. S. **Ryland**: An improved subjective test for astigmatism. The test apparatus consists of an opaque disc perforated along two diameters at right angles with a series of square apertures. These apertures and the distances between them subtend angles of $1'$ at the usual testing distance. The plate is illuminated by diffused light from the rear.

DUBLIN.

Royal Dublin Society, May 23.—Dr. F. E. Hackett in the chair.—H. A. **Lafferty**, and G. H. **Pethybridge**: On a Phytophthora parasitic on apples which has both amphigynous and paragynous antheridia; and on allied species which show the same phenomenon. The Phytophthora in question is *P. Syringæ* (Klebahn) and not *P. Cactorum* (Schroet), which has several times been found causing decay of apples both in Europe and America. In addition to these two species *P. Fagi* also produces two kinds of antheridia. The grouping of the twenty-two species of Phytophthora is discussed and the elimination of the recently erected genus Nozemia proposed. The economic significance of this form of apple rot is small.—A. G. G. **Leonard** and Miss A. M. **Richardson**: The occurrence of helium and argon in the boiling well at St. Edmundsbury, Lucan, Co. Dublin. The gas from the well consists almost completely of "nitrogen" with small quantities of carbon dioxide. The removal of nitrogen and carbon dioxide leaves a small amount of residual gas consisting of argon and helium. The percentages of argon and helium are 0·95 and 0·074 respectively.—H. H. **Poole**: Some further notes on the distribution of activity in radium therapy. Tables are given showing the approximate distribution of activity for different arrangements of emanation needles, and the skin activities with tubular applicators of various diameters and thicknesses.

PARIS.

Academy of Sciences, May 29.—M. Albin Haller in the chair.—The president announced the death of M. Ernest Solvay, at the age of 84 years.—L. **Maquenne** and E. **Demoussy**: Plant growth in media poor in oxygen. Seeds of radish, pea, wheat, and rape germinated in sterile sand and wholly submerged in running water gave seedlings possessing an assimilation capacity comparable with a normal plant. If a small proportion of carbon dioxide is added, the weight of the dry-plant material is higher than, or at least equal to, the weight of the original seed. The leaves of certain species of plants (sorrel, Aucuba) can retain their vitality in the absence of air for a long period.—M. **Riquier**: The singular integral figures of partial systems of the first order to which the method of integration of Jacobi applies.—E. **Mathias**, C. A. **Crommelin**, and H. Kamerlingh **Onnes**: The heat of vaporisation and the difference $m'-m$ of the specific heats in the saturated state for argon, oxygen, nitrogen, and hydrogen.—M. Henri Lebesgue was elected a member of the Section of Geometry in the place of the late C. Jordan.—F. H. **Murray**: Drawing arcs of circles of large radius.—J. W. **Lindeberg**: The law of Gauss.—P. J. **Myrberg**: Automorph functions of several independent variables.—M. **Ferrier**: The deviations of light rays passing in the neighbourhood of a star. A theoretical study of the deviations caused by the atmosphere of a star. This is superposed on the Einstein effect, and in certain cases might mask the latter. The cases of the Earth and Moon are worked out in detail.—J. **Guillaume**: Observations of the Skjellerup comet, made with the *coudé* equatorial of the Observatory of Lyons. Positions are given for six consecutive days, May 19-24, together with the positions of the comparison stars. The comet is vaguely circular, of about 0·5′ diameter and without marked condensation.—Mlle. O. **Jasse**: Observations of the comet 1922b (Skjellerup), made at the Observatory of Marseilles (Eichens equatorial, 26 cm. aperture). One position is given, for May 24.—A. **Danjon**: A new interference method for measuring the apparent diameter of stars. The Jamin system of thick plates is utilised. If the star has no appreciable apparent diameter it disappears completely when passing over the centre of a dark band, but if there is an appreciable disc the extinction will be incomplete. A formula is given for the maximum and minimum brightness, and the determination of the diameter is reduced to the photometric measurement of the maximum and minimum brightness when the star is observed through the interferometer. Experiments have been carried out on an artificial star, but the successful application of the method will depend on the influence of the movements of the atmosphere.—Gustave **Guillaumin**: The plane lines of slipping of pulverent, coherent, or plastic bodies.—Jean **Lecarme**: Experiments relating to the course of a pendulum and a chronometer, carried out at Chamonix and at the Mont Blanc Observatory, between August 1 and September 10, 1921. The chronometers were checked by the wireless signals from the Eiffel Tower and showed an unexplained loss of 30 seconds per day. The values of g at Paris, Chamonix, and the summit of Mont Blanc were determined by the pendulum and compared with the calculated figures.—S. **Zaremba**: The relativist conception of space.—Louis G. **Stokvis**: The circular diagrams of unbalanced triphase systems and the definition of their degree of lack of balance.—H. **Weiss** and P. **Henry**: The influence of the time factor on the interpenetration of solids by chemical reaction. Experiments were made on two pairs of metals—silver-antimony and copper-antimony. The depth of interpenetration was determined for varying times and temperatures, and the results given graphically.—Joseph **Blondeau**: Study of some dialkyl benzyl cyanides and the corresponding alcohols, amides, amines, and acids.—R. **Locquin** and Sung **Wouseng**: The action of acetylene on the sodium derivatives of ketones and the preparation of the dialkylethinylcarbinols. The sodium derivative of the ketone was prepared by the action of sodium amide on the ketone in ether or benzene. This is then allowed to react with purified acetylene with continual agitation and the product decomposed with ice-water. Starting with the ketone $R.CO.R'$ the alcohol $R.R'.C(OH).C{\equiv}CH$ is obtained. The generality of the method is shown by its application to four ketones.—L. **Blaringhem**: Sex heredity in *Lychnis vespertina*.—A. **Lécaillon**: The fecundity of hybrids obtained by crossing the male *Dafila acuta* with the female *Anas boschas*. These hybrids form an exception to the general rule and are fertile.—W. R. **Thompson**: Mathematical study of the action of insect-destroying parasites. Duration of the parasitic cycle and the increase of the proportion of parasite hosts.—Emile F. **Terroine** and René **Wurmser**: The energy yield in the growth of *Aspergillus Niger*. This mould growing in a glucose medium, after certain corrections are made, accounts for 66-70 per cent. of the energy of the glucose. It is pointed out that Fingerling, Köhler, and Reinhardt have obtained values of the same order in the case of the growth of the pig.—MM. Georges **Bourguignon** and **Conduché**: Experiments on the introduction of the iodine ion by electrolysis in man, and its elimination by the urine.

SYDNEY.

Linnean Society of New South Wales, March 29.—Mr. G. A. Waterhouse, president, in the chair.—G. A. **Waterhouse** (Annual Address): (I.) The need for a zoological survey of Australia. The fauna of Australia is a national asset, although probably the finest collections of the Australian fauna will be found in museums outside Australia. Systematic zoological survey has not been attempted. Im-

mediate steps might be taken by the Commonwealth Government to institute a Federal Museum, in which could be gathered together specimens of Australian animals and accurate information concerning their distribution. Doubtless many private individuals would donate part of their collections to form the nucleus of such a display of the Australian fauna. (II.) Breeding experiments with the Satyrine genus Tisiphone. The genus Tisiphone is confined to the coast and Main Dividing Range of eastern and south-eastern Australia, and the *T. abeona* extends, with six sub-species, from southern Queensland into Victoria, but specimens from a small area round Port Macquarie appeared to be natural hybrids. In October 1920, pupæ and larvæ of *T. morrisi* were obtained from Urunga, at the mouth of the Bellingen River, and reared. Similarly, larvæ of *T. abeona* from near Sydney were reared. Crosses were obtained and the work carried to the third generation. The results afford some proof that *T. joanna* is a natural hybrid. The distribution of Tisiphone may help in elucidating the physiography of eastern Australia in Tertiary time. Possibly before the uplifting movement at the end of the Pliocene the ancestor of Tisiphone was in eastern Australia, and became restricted to the higher elevations where moisture was more abundant. The Cassilis Gap was responsible for discontinuous distribution and development took place independently north and south of this Gap. Later the northern and southern forms were able to reach the coast, and where they met the very complex race *T. joanna* was developed.—W. F. **Blakely**: The Loranthaceæ of Australia. Pt. I. The range and origin of the family were given and the seeds and germination, parasitism, union with the host, adventitious roots, mimicry, dispersal and agents of distribution described.—Vera **Irwin-Smith**: Notes on nematodes of the genus Physaloptera, with special reference to those parasitic in reptiles. Pt. II. A review of the Physaloptera of lizards. The characters useful in the determination of the various species received particular attention.—Marguerite **Henry**: A monograph of the freshwater Entomostraca of New South Wales. Pt. I. Cladocera. Descriptions of fifty species, belonging to seventeen genera, were given; five of the species are new and the presence of others in Australia is recorded for the first time.

April 26.—Mr. G. A. Waterhouse, president, in the chair.—H. J. **Carter**: Australian Coleoptera: Notes and new species. No. ii. A series of Chalcotænia, together with a table of the Australian species, and some Australian species of Stigmodera are described. Eight species of Buprestidæ, eleven species of Tenebrionidæ, and one genus and five species of Cistelidæ are new.—F. **Muir**: A new genus of Australian Cixiidæ (Homoptera). The new genus is allied to Leptoclamys Kirk. Specimens were collected near Sydney. The abnormal development of the front legs indicates that the nymph is probably subterraneous in its habits.—T. Harvey **Johnston** and O. W. **Tiegs**: New gyrodactyloid trematodes from Australian fishes, together with a reclassification of the super-family Gyrodactyloidea. The first species of monogenetic Trematoda belonging to the Gyrodactylidæ from Australasia are described. The hosts comprise seven species of freshwater fish and five species of marine fish. A new super-family and five new sub-families are proposed. In addition to the new Australian genera five others are proposed, mainly for North American species. All the known freshwater species show affinities with Australian marine species, thus emphasising the marine origin of the Australian freshwater fish fauna.

Official Publications Received.

Fifty-third Annual Report of the Trustees of the American Museum of Natural History, for the Year 1921. Pp. 259. (New York.)
